COMISSÃO EXAMINADORA

Prof. Dr. Daniel Martins de Souza (Orientador)

Prof. Dr. Marcelo Bispo de Jesus

Prof. Dr. Adriano Silva Sebollela

Os membros da Comissão Examinadora acima assinaram a Ata de Defesa, que se encontra no processo de vida acadêmica do aluno.

A Ata da defesa com as respectivas assinaturas dos membros encontra-se no SIGA/Sistema de Fluxo de Dissertação/Tese e na Secretaria do Programa de Pós Graduação em Biologia Funcional e Molecular da Unidade (Instituto de Biologia).

Dedicatória

Dedico essa dissertação aos meus pais, que sempre me apoiaram, incentivaram e me deram forças em todos os momentos.

AGRADECIMENTOS

O presente trabalho foi realizado com apoio da Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Código de Financiamento 001.

Agradeço o apoio financeiro da Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP), processo nº 2018/10362-0.

À Fapesp e ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), processo nº 157265/2018-8.

Ao meu orientador, prof. Dr. Daniel Martins de Souza, por toda orientação e oportunidades que me proporcionou ao longo do mestrado. Obrigada também por toda compreensão e aprendizado que obtive durante esses anos.

À minha coorientadora, Dra. Valéria de Almeida, pelas orientações no desenvolvimento do projeto e em toda a parte experimental. Obrigada por esse exemplo de cientista dedicada e que ama ensinar. Obrigada também por toda compreensão, companhia e aprendizado que obtive durante esses dois anos, sou extremamente grata.

Aos meus colegas do Laboratório de Neuroproteômica, pela companhia e ajuda profissional. Agradeço em especial à Dra. Fernanda Crunfli pelas orientações em relação ao desenvolvimento dos experimentos; à Aline Valença, Brad Smith, Licia Costa, Pamela Carlson e Livia Ramos pela amizade, ajuda e apoio nesses dois anos; à Danielle Junqueira pela amizade, companhia nos experimentos e na vida; ao Paulinho pelo auxílio nos experimentos de digestão em gel; e a todos do laboratório pela companhia, conversas e trocas de aprendizado.

Aos meus pais, Roseli e Luiz, que sempre me deram forças e apoio para seguir todos os meus sonhos, vocês sempre serão minha inspiração. À minha irmã, Giovanna, que sempre me apoiou e incentivou em todas as minhas escolhas. E a todos os meus familiares que estiveram presentes em todos os momentos.

A todos, minha eterna gratidão.

RESUMO

A esquizofrenia é uma desordem mental que afeta 20 milhões de pessoas em todo o mundo. A desconectividade neural, assim como alterações na substância branca, nos oligodendrócitos e na integridade de mielina, podem estar relacionadas aos sintomas dessa desordem. Neste contexto, os modelos tóxicos de desmielinização são ferramentas utilizadas para a compreensão dos mecanismos envolvidos nestas alterações. Por sua vez, abordagens proteômicas são de suma importância para a compreensão dos processos envolvidos em diferentes distúrbios neurológicos, através da compreensão das bases bioquímicas, por meio da identificação de vias e proteínas diferencialmente expressas. Desta forma, no presente trabalho foi utilizado o modelo farmacológico induzido por cuprizona em culturas de células de oligodendrócitos humanos (linhagem MO3.13), com intuito de testar os efeitos da benztropina, molécula capaz de induzir mielinização e diferenciação dos oligodendrócitos, e compará-los com os potenciais efeitos protetores ou tóxicos dos antipsicóticos (clozapina e haloperidol) e do canabidiol, os quais afetam os oligodendrócitos de maneira distinta. Após o tratamento dos oligodendrócitos com as drogas citadas acima, foi realizada a extração e digestão do proteoma para análise por meio de nano-cromatografia acoplada à espectrometria de massas, com a finalidade de investigar as proteínas e vias envolvidas nos tratamentos com estes compostos. Nossos resultados indicam que a cuprizona é capaz de induzir efeito citotóxico em oligodendrócitos MO3.13 através de distúrbios em processos biológicos relacionados ao metabolismo energético e de lipídios, à processos genéticos, e à sinalização de fatores de crescimento. Já a administração de antipsicóticos, canabidiol e benztropina podem modular vias relacionadas ao metabolismo, ao ciclo celular e à fatores genéticos, as quais estão relacionadas com os efeitos tóxicos induzidos pela cuprizona, indicando os seus potenciais efeitos em atenuar a toxicidade desta droga. Apesar da complexidade da fisiopatologia deste transtorno não ser totalmente representada no modelo tóxico por cuprizona, esses resultados fornecem informações sobre os mecanismos dos antipsicóticos e do canabidiol contra os efeitos tóxicos da cuprizona e suas implicações no desenvolvimento de novos alvos terapêuticos e tratamento para a esquizofrenia.

ABSTRACT

Schizophrenia is a psychiatric disorder that affects 20 million people worldwide. Neuronal dysconnectivity can be correlated to symptoms of this disorder, which is related to oligodendrocytes and myelin abnormalities in white matter. In this context, toxic models of demyelination are used to understand the mechanisms involved in these alterations. To achieve this, proteomic approaches are important to understand processes involved in neurological disorders through the elucidation of biochemical bases and identification of differentially expressed pathways and proteins. In this context, we developed an *in vitro* assay of cuprizone-mediated death in a human oligodendrocyte cell line (MO3.13) to test the effect of benztropine, a molecule that enhances myelination and oligodendrocyte differentiation, and compared its effect with the potential protective effects of antipsychotics (clozapine and haloperidol) and cannabidiol. After the treatments mentioned above, the proteomes were extracted and digested for analysis by nano-chromatography coupled to mass spectrometry to investigate the proteins and pathways affected in oligodendrocytes treated by these drugs. We confirmed that the *in vitro* model for cuprizone cell death impairs MO3.13 oligodendrocyte viability through disturbances of several biological processes, including energy and lipid metabolism, genetic processes and growth signaling. Furthermore, the administration of antipsychotics, cannabidiol, and benztropine seems to modulate metabolism, genetic factors, cell cycle and cell signaling, which are related to cuprizone-induced cell death, indicating their potential to act against the cuprizone toxic effect. In conclusion, although modeling oligodendrocyte death with cuprizone does not represent the entirety of the pathophysiology of the disorder, these results provide insight into the mechanisms related to antipsychotics' and cannabidiol's effects against cuprizone toxicity and their implications for developing new pharmaceutical targets and treatment options for schizophrenia.

ÍNDICE DE FIGURAS

INTRODUÇÃO

Figura 1. Representação do sistema endocanabinoide, adaptado de Seabra et al., 2018.

Figura 2. Esquema dos principais componentes do Synapt G2-Si HDMS, incluindo a fonte de ionização, analisadores de massas e a cela de mobilidade iônica (trap, câmara de mobilidade e transfer), adaptado de Waters Corporation.

Figura 3. Representação das seguintes etapas experimentais: tratamento e co-tratamento de OLs MO3.13 com cuprizona e/ou haloperidol (HAL), clozapina (CLZ), cannabidiol (CBD) e benztropina (BENZ), seguido das etapas de extração e digestão das proteínas, quantificação dos peptídeos, análise de espectrometria de massas, processamento de dados e análise *in silico*.

CAPÍTULO I

Figure 1. Schematic representation of the main signaling processes and potential novel treatment targets involved with oligodendrocyte dysfunction in schizophrenia. Antipsychotics acting via inhibition of D2 and 5-HT2A receptors are the main therapeutic strategy currently used in schizophrenia treatment. D-amino acids and memantine are shown here as potential targets aiming for improvements in the glutamatergic signaling dysfunction. Endocannabinoids and the GSK3b inhibitor, lithium, contribute to the MEK/ERK1/2-MAPK and PI3K/Akt/mTOR signaling pathways, which are important for oligodendrocyte proliferation and differentiation. Moreover, aiming to attenuate oxidative damage, antioxidants such as N-acetylcysteine may consist of potential therapeutic agents.

CAPÍTULO II

Figure 1. Bar graph of enriched biochemical pathways in MO3.13 cells treated with benztropine, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are represent between 10^{-20} to 10^{-2} .

Figure 2. Chord diagram where purple curves link identical genes between clozapine, cannabidiol, haloperidol, and benztropine treatment (A); and a heatmap of enriched pathways in OLs treated with these drugs (B), created in Metascape.

Figure 3. Proteins differentially expressed in OLs treated with 10 μ M of cuprizone (CUP) for 48 hours, compared to the vehicle (VEH), created with ClustVis.

Figure 4. Prospective network interaction of proteins differentially expressed on oligodendrocytes treated with cuprizone. The network was generated in Cytoscape from differentially expressed proteins resulting from cuprizone treatment (10 μ M, 48h). Colored lines represent a strong interaction; red spheres are upregulated proteins; blue spheres are downregulated proteins. All colored spheres represent $p < 0.05$; to better show potential interconnectivity, gray spheres were added with a higher cutoff ($p < 0.10$).

Figure 5. Bar graph of the enriched pathways in OLs resulting from cuprizone treatment (10 μ M, 48h), generated with Metascape.

Figure 6. Chord diagram where purple curves link identical genes between cuprizone treatment (Cup) and co-treatment with cuprizone and clozapine (CupClz), cannabidiol (CupCBD), haloperidol (CupHal) or benztropine (CupBenz) (A); and a heatmap of enriched pathways of oligodendrocytes co-treated with cuprizone and haloperidol, cannabidiol, clozapine, or benztropine (B), created in Metascape.

MATERIAL SUPPLEMENTAR

Figure S1. A MTT assay was used to measure the percentage of live M03.13 cells at 48h with growth medium (DMEM), Vehicle (DMSO, 0.3%), and increasing cuprizone concentrations. (****, $P < 0.0001$; $n = 6$ wells/condition).

Figure S2. A MTT assay was used to measure the percentage of live M03.13 cells after 8h in growth medium (DMEM), Vehicle (haloperidol and cannabidiol, DMSO, 0.3%; clozapine, DMSO, 0.4%; benztropine was diluted in water), and increasing concentrations of haloperidol (A), clozapine (B), cannabidiol (C), or benztropine (D) (*, $P \leq 0.05$; ***, $P < 0.001$; ****, $P < 0.0001$; $n = 6$ wells/condition).

Figure S3. Bar graph of enriched biochemical pathways in M03.13 cells treated with haloperidol, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are representing between 10^{-20} to 10^{-2} .

Figure S4. Bar graph of enriched biochemical pathways in M03.13 cells treated with clozapine, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are representing between 10^{-20} to 10^{-2} .

Figure S5. Bar graph of enriched biochemical pathways in MO3.13 cells treated with cannabidiol, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are representing between 10^{-20} to 10^{-2} .

Figure S6. The network of enriched terms colored by cluster ID (A) and by network-enriched terms, represented as a pie chart (B) in treatment with cuprizone and co-treatments with cuprizone and haloperidol, clozapine, cannabidiol or benztropine, created with Metascape.

LISTAS DE TABELAS

CAPÍTULO II

Table 1. Biochemical pathways highlighted in treatment with cuprizone (10 μ M, 48h), generated with Reactome.

MATERIAL SUPLEMENTAR

Table S1. List of proteins identified, quantified, differentially regulated, upregulated, and downregulated in treatments and co-treatments with cuprizone (Cup) and haloperidol (Hal), clozapine (Clz), cannabidiol (CBD), or benztropine (Benz).

Table S2. List of the differentially expressed proteins (by ANOVA, $p \leq 0.05$) seen in response to cuprizone treatment, compared with the changes seen in response to cuprizone and either haloperidol (Hal), clozapine (Clz), cannabidiol (CBD), or benztropine (Benz). Hyphens represent that the protein was not identified or not quantifiable in that sample. Highlighted p-values represent a change (ANOVA, $p \leq 0.05$) in the opposite direction of that induced by cuprizone, indicating a reversal of its putative toxic effects.

Table S3. Biochemical pathways highlighted in co-treatment with 10 μ M of cuprizone for 24 hours and 1 μ M of haloperidol for an additional 24 hours (CupHal), compared to cuprizone treatment alone, generated by Reactome.

Table S4. Biochemical pathways highlighted in co-treatment with 10 μ M of cuprizone for 24 hours and 1 μ M of clozapine for an additional 24 hours (CupClz), compared to cuprizone treatment alone, generated by Reactome.

Table S5. Biochemical pathways highlighted in co-treatment with 10 μ M of cuprizone for 24 hours and 1 μ M of cannabidiol for an additional 24 hours (CupCBD), compared to cuprizone treatment alone, generated by Reactome.

Table S6. Biochemical pathways highlighted in co-treatment with 10 μ M of cuprizone for 24 hours and 1 μ M of benztropine for an additional 24 hours (CupBenz), compared to cuprizone treatment alone, generated by Reactome.

Table S7. Biochemical pathways highlighted in treatment with 1 μ M of haloperidol for 24 hours (Hal) compared to vehicle samples, generated by Reactome.

Table S8. Biochemical pathways highlighted in treatment with 1μM of clozapine for 24 hours (Clz) compared to vehicle samples, generated by Reactome.

Table S9. Biochemical pathways highlighted in treatment with 1μM of cannabidiol for 24 hours (CBD) compared to vehicle samples, generated by Reactome.

Table S10. Biochemical pathways highlighted in treatment with 1μM of benztropine for 24 hours (Benz) compared to vehicle samples, generated by Reactome.

Table S11. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in MO3.13 oligodendrocytes exposed to cuprizone (CUP; 10μM, 48h) compared to vehicle (VEI).

Table S12. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in MO3.13 oligodendrocytes treated with haloperidol (Hal; 1μM, 24h) compared to vehicle (VEI).

Table S13. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in MO3.13 oligodendrocytes treated with clozapine (Clz; 1μM, 24h) compared to vehicle (VEI).

Table S14. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in MO3.13 oligodendrocytes treated with cannabidiol (CBD; 1μM, 24h) compared to vehicle (VEI).

Table S15. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in MO3.13 oligodendrocytes treated with benztropine (Benz; 1μM, 24h) compared to vehicle (VEI).

Table S16. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in co-treatment 10μM of cuprizone for 24 hours and 1μM of haloperidol for an additional 24 hours (CupHal), compared to cuprizone treatment alone (Cup).

Table S17. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in co-treatment 10μM of cuprizone for 24 hours and 1μM of clozapine for an additional 24 hours (CupClz), compared to cuprizone treatment alone (Cup).

Table S18. List of proteins differentially expressed (by ANOVA, $p \leq 0.05$) in co-treatment 10μM of cuprizone for 24 hours and 1μM of cannabidiol for an additional 24 hours (CupCBD), compared to cuprizone treatment alone (Cup).

LISTAS DE ABREVIATURAS

2-AG - 2-araquidonilglicerol

2D-GE - Eletroforese bidimensional

2D-PAGE - Gel de eletroforese bidimensional de poliacrilamida

ABHD6 ou ABHD12 - Serinas hidrolases, α , β -hidrolase domínios proteínas 6 e 12

ACN - Acetonitrila

AEA – Anandamida, N-arachidonoyl ethanolamine

AF - Ácido fórmico

Ambic - Ammonium bicarbonate

ATP – Adenosine triphosphate

BDNF - Brain-derived neurotrophic factor

BENZ - Benztropine

CB1 - Receptores de canabinoides do tipo 1

CB2 - Receptores de canabinoides do tipo 2

CBD - Canabidiol, cannabidiol

CID - Dissociação induzida por colisão

CLZ - Clozapine

CNP - 2, '3'-cyclic-nucleotide-3'-phosphodiesterase

CNS - Central nervous system

CUP ou CPZ - cuprizona, cuprizone

CupBenz - Co-treatment with cuprizone (10 μ M; 48h) and benztropine (1 μ M; 24h)

CupCBD - Co-treatment with cuprizone (10 μ M; 48h) and cannabidiol (1 μ M; 24h)

CupClz - Co-treatment with cuprizone (10 μ M; 48h) and clozapine (1 μ M; 24h)

CupHal - Co-treatment with cuprizone (10 μ M; 48h) and haloperidol (1 μ M; 24h)

DAG - Diacylglycerol

DAGL - DAG lipase

DIA - Análise independente de dados, data-independent analysis

DISC1 - Disrupted-in-schizophrenia 1

DMEM – Dulbecco's Modified Eagle Medium

DSM-5 - Manual diagnóstico e estatístico de transtornos mentais

DTT - Dithiothreitol stock

EAE - Encefalomyelitis autoimmune experimental

ERK1/2 - Signal-regulated kinases-1 and -2

ESI - Ionização por electrospray

FAAH - Enzima hidrolase de amida de ácidos graxos

FDR – False discovery rate

GalC - Galactocerebroside C

GPR55 - G protein-coupled receptor 55

GSH - Glutathione

GSK3b - Glycogen synthase kinase 3b

HAL - Haloperidol

ICD - Classificação estatística internacional de doenças e problemas relacionados à saúde

IGF-1 - Insulin-like growth factor 1

IT - Ion traps

LC-MS – Cromatografia líquida acoplada à espectrometria de massas

MAG - Glicoproteína associada à mielina, myelin associated glycoprotein

MALDI - Ionização dessorção a laser auxiliada por matriz

MAGL - Lipases monoacilglicerol

MAPKs - Mitogen-activated protein kinases

MBP - Proteína básica de mielina, myelin basic protein

MCT-1 - Monocarboxylate transporter 1

MCT-2 - Monocarboxylate transporter 2

MOG - Glicoproteína da mielina de oligodendrócitos, myelin oligodendrocyte glycoprotein

MS - Espectrometria de massas

mTOR - Mammalian target of rapamycin

NAAA - Enzima N-acetil-etanolamina-hidrólise ácida amidase

NAD⁺ - Dinucleotídeo de nicotinamida e adenina, nicotinenamide adenine dinucleotide

NAPE - N-acil-fosfatidiletanolamina

NAPE-PLD - Fosfolipase-D-específica de NAPE

NG2 - Neuron-glial antigen 2

NGR - Nogo Receptor

NGF - Nerve growth factor

NMDA - N-metil-D-Aspartato

NPC - Neural progenitor cells

NRG1 - Neuregulin 1

NSC - Neural stem cells

Olig2 - Oligodendrocyte lineage transcription factor 2

OLs - Oligodendrócitos, oligodendrocytes

OPCs - Células precursoras de oligodendrócitos, oligodendrocytes progenitor cells

PBS - Phosphate-buffered saline

PPARs - Peroxisome proliferator activated nuclear receptors

PFC - Prefrontal cortex

PI3K - Phosphoinositide 3-kinase

PLP - Proteína proteolipídica de mielina, proteolipid protein

PPI - Prepulse inhibition

Q - Quadropolo

QKI - Quaking I

QUE - Quetiapine

ROS - Espécies reativas de oxigênio

Rtn4 - Reticulon 4

SNC – Sistema Nervoso Central

SVZ - Subventricular zone.

THC - Δ -9-tetrahydrocannabinol

TOF - Time of flight mass analyzers

TRPV1 - Transient receptor potential vanilloid-1 channel

1. INTRODUÇÃO

1.1 A esquizofrenia

A esquizofrenia é uma desordem mental grave, crônica e incurável que atinge 1% da população mundial. O início deste transtorno ocorre entre o final da adolescência e o início da vida idade adulta (Owen et al., 2016). Estudos demonstram que pacientes com esquizofrenia têm expectativa de vida de 12 a 15 anos menor do que a da população geral, já que tal distúrbio apresenta alta frequência de suicídio e problemas cardiovasculares (Bruijnzeel et al., 2014; van Os & Kapur, 2009). Os sintomas característicos da esquizofrenia são os sintomas positivos que incluem alucinações, delírios e desorganização do pensamento, os sintomas negativos como a perda motivacional e vivacidade emocional, e os sintomas cognitivos, incluindo comprometimento da memória e de funções executivas (Lewis & Lieberman, 2000; Tarpada & Morris, 2017).

O diagnóstico da esquizofrenia é baseado na anamnese realizada pelo o médico, com base na história e estado mental do paciente. A categorização da mesma é realizada com base no Manual Diagnóstico e Estatístico de Transtornos Mentais (DSM-5) ou através da Classificação Estatística Internacional de Doenças e Problemas Relacionados à Saúde (ICD) (Kahn et al., 2015; Owen et al., 2016). O tratamento medicamentoso de indivíduos com esquizofrenia é baseado na administração de antipsicóticos, os quais atuam efetivamente no tratamento dos sintomas positivos, entretanto possui baixa eficácia no tratamento dos sintomas negativos e cognitivos (Bruijnzeel et al., 2014; van Os & Kapur, 2009). Os antipsicóticos de primeira geração (convencionais ou típicos) descobertos nos anos 1950, como o haloperidol, são antagonista dos receptores D₂, sendo efetivos na redução dos sintomas positivos, porém conduzem a certos efeitos colaterais extrapiramidais (Howes et al., 2015; Howes & Kapur, 2009). Os antipsicóticos de segunda geração (atípicos) como clozapina, risperidona, olanzapina e quetiapina, apresentam afinidade aos receptores D₂ e aos receptores 5-HT₂, sendo mais eficientes na redução dos sintomas negativos, mas podem causar aumento de peso e sedação, quando comparados com os de primeira geração (Leucht et al., 2009; van Os & Kapur, 2009). Neste contexto, os aspectos heterogêneos e multifatorial da esquizofrenia, em conjunto com o conhecimento limitado quanto a causa e a fisiopatologia deste transtorno, dificultam o diagnóstico e a escolha adequada ao tratamento (Nascimento & Martins-de-Souza, 2015).

1.1.1 Fisiopatologia da esquizofrenia

A esquizofrenia é considerada multifatorial, sendo determinada pela interação de fatores genéticos e ambientais, como estresses ocorridos durante a vida fetal (hipóxia, estresse materno e deficiência nutricional) e na infância (Owen et al., 2016). A fisiopatologia desta desordem engloba distúrbios moleculares no sistema nervoso, metabólico, imune e endócrino (Collip et al., 2011; Martins-de-Souza et al., 2011; Pouget et al., 2019; Saia-Cereda et al., 2015). Diversas hipóteses são postuladas para compreender a etiologia da esquizofrenia, porém as hipóteses glutamatérgica e dopaminérgica estão entre as teorias mais estudadas e aceitas, embora evidências sugiram alterações em outros sistemas como o GABAérgico, serotoninérgico, colinérgico e endocanabinoide (Friedman, 2004; Muguruza et al., 2019; Steiner et al., 2016; Yang & Tsai, 2017).

A hipótese dopaminérgica foi postulada na década de 1960, quando foi descoberto o potencial efeito do antipsicótico clorpromazina em atenuar os sintomas positivos em pacientes com esquizofrenia (Yang & Tsai, 2017). Diversos estudos suportam a hipótese que o sistema dopaminérgico estão relacionados com os sintomas psicóticos em pacientes com esquizofrenia (Mackay et al., 1982; Howes & Kapur, 2009). Estudos em cérebros *post-mortem* de pacientes sugerem alterações neuropatológicas na esquizofrenia, incluindo aumento nos níveis de dopamina e na densidade dos receptores D₂ (Mackay et al., 1982). Além disso, o aumento da atividade de dopamina foi observada predominantemente nas regiões do estriado e mesencéfalo em pacientes com alto risco de psicose ou em pacientes que desenvolveram este sintoma mais tardiamente (Edwards et al., 2016; Egerton et al., 2013; Laruelle et al., 1996; Howes et al., 2013). Neste contexto, os antipsicóticos utilizados no tratamento dessa desordem apresentam afinidade pelo receptor de dopamina, bloqueando sua atividade e amenizando os sintomas positivos (Howes et al., 2015; Howes & Kapur, 2009).

Por outro lado, o glutamato é um neurotransmissor excitatório e mais abundante no cérebro. A ação desse neurotransmissor é mediada por receptores metabotrópicos e ionotrópicos, dentre eles os receptores do tipo NMDA (N-metil-D-Aspartato). Suas vias se ligam as regiões do córtex pré-frontal, tálamo e lobo temporal, as quais se encontram alteradas na esquizofrenia (Gao et al., 2000; Goff & Coyle, 2001; Ibrahim et al., 2000). Estudos relatam níveis reduzidos de glutamato no líquido cefalorraquidiano e níveis elevados de metabólitos de glutamato no hipocampo e na região cortical frontal em pacientes com esquizofrenia (Egerton et al., 2017; Howes et al., 2015). Ademais, foi demonstrado que

animais tratados com fenciclidina, um antagonista dos receptores NMDA, apresentam alterações nas expressões de genes no córtex pré-frontal, região relacionada à disfunção cognitiva na esquizofrenia, dentre eles alterações nas expressões de transcritos relacionados à mielina e à linhagens de oligodendrócitos (OLs) (Kaiser et al., 2004). Desta forma, a hipofunção dos receptores NMDA podem desempenhar um grande papel na fisiopatologia da esquizofrenia (Cohen et al., 2015; Paz et al., 2008).

Outras linhas de estudos relacionam as anormalidades na substância branca e a desconectividade neural à fisiopatologia desse transtorno, os quais podem estar relacionados às disfunções na mielinização acarretados por distúrbios em OLs (Cassoli et al., 2015; Jørgensen et al., 2016; Vikhrev et al., 2016). Estudos *post-mortem* e de neuroimagem indicam alterações na mielinização, na área cortical e na substância branca, assim como a redução do número de OLs em pacientes com esquizofrenia (Jørgensen et al., 2016; Mighdoll et al., 2015). Além disso, as anormalidades na conectividade neural e na substância branca podem estar correlacionadas com os sintomas positivos, negativos e cognitivos de pacientes com este transtorno (Bernard et al., 2015; Kochunov et al., 2017; Orban et al., 2017; Saito et al., 2018). Sendo assim, estudos demonstram que as alterações na substância branca, assim como as alterações em OLs e na mielina, podem estar relacionadas com os sintomas da esquizofrenia devido à degradação funcional de importantes circuitos neurais.

1.1.2 O papel dos oligodendrócitos e da mielina na esquizofrenia

Os OLs são células gliais responsáveis pela mielinização dos axônios no sistema nervoso central (SNC), expressando genes que codificam as proteínas da mielina de maneira específica e controlada. Estas células têm origem a partir de células neuroectodérmicas presentes nas zonas sub ventriculares, com posterior migração para as zonas corticais e para substância branca, seguido da maturação em células mielinizantes (Baumann & Pham-Dinh, 2001; Buntix et al., 2003; Pfeiffer et al., 1993). Os processos de oligodendrogênese e de mielinização requerem a ativação de diversas vias de sinalização e da interação com outras células da glia, a fim de fornecer precursores de colesterol e nutrientes para a bainha de mielina, além de propiciar quimiocinas e fatores de crescimento que influenciam os processos de sobrevivência, proliferação, migração e maturação dos OLs (Baror et al., 2019; Camargo et al., 2017; Dziembowska et al., 2005). A mielinização realizada pelos OLs é essencial para a propagação do potencial de ação no axônio, pois devido à composição única (rica em lipídeos e baixo teor de água), e à estrutura segmentar da mielina, a transdução de sinal

elétrico é mais rápida e eficiente nas fibras nervosas mielinizadas (Baumann & Pham-Dinh, 2001; Peferoen et al., 2014; Simons & Nave, 2015). Além disso, essas células possuem um papel importante no metabolismo energético axonal, como a liberação de lactato ou piruvato para o espaço peri-axonal via MCT-1 (*monocarboxylate transporter 1*), que logo em seguida entram nos axônios através de MCT-2 (*monocarboxylate transporter 2*) para a geração de ATP mitocondrial axonal (Philips & Rothstein, 2017; Saab et al., 2013).

Outros estudos indicam que o lactato é capaz de promover a homeostase de ATP nos OLs, sendo importante para a formação e geração de mielina (Rinholm et al., 2011). Estudos proteômicos revelam alterações em proteínas e vias bioquímicas relacionadas ao metabolismo energético, como também demonstrado em estudos de imagens, os quais relatam níveis reduzidos nas taxas metabólicas de glicose em diferentes núcleos talâmicos em pacientes com esquizofrenia (Hazlett et al., 2004; Zuccoli et al., 2017). A privação energética pode inibir eventos de mielinização e acarretar em desmielinização, por meio da limitação da disponibilidade de substratos para a síntese de lipídios na mielina (Rinholm et al., 2011). Estudos com amostras *post-mortem* do córtex pré-frontal indicam uma mielinização anormal em pacientes com esquizofrenia (Migdall et al., 2015). Ademais, foram relatados desregulações em constituintes essenciais da bainha de mielina, como as proteínas MBP (proteína básica de mielina) e MOG (glicoproteína da mielina de oligodendrócitos) (Saia-Cereda et al., 2015), e alterações nos padrões de RNA mensageiros (mRNA), transcritos e proteínas de OLs (Cassoli et al., 2015).

O ciclo de vida dos OLs consiste em processos altamente regulados e controlados, e estão relacionados a conectividade cerebral adequada (Barateiro & Fernandes, 2014). A desconectividade neural, assim como outras alterações da substância branca na esquizofrenia, podem estar relacionadas à OLs anormais. Descobertas referente à neuropatologia da substância branca no distúrbio em questão incluem a diminuição da densidade de OLs, alterações na distribuição espacial dos mesmos e variações na morfologia dessas células (Bernstein et al., 2015). Estudos indicam que disfunções nos OLs no hipocampo causam alterações no neurocircuito entre o hipocampo e hipotálamo, acarretando em distúrbios cognitivos em pacientes com esquizofrenia (Falkai et al., 2016; Falkai et al., 2020). Além disso, a mielinização anormal e disfunções nas sinapses podem ser correlacionadas com distúrbios na funcionalidade neuronal e glial (Mirnics et al., 2000; Takahashi et al., 2011).

Além dos estudos citados, foram relatadas anormalidades nos processos de diferenciação de células precursoras de oligodendrócitos (OPCs) e de oligodendrogênese na esquizofrenia (Hattori et al., 2014; Santos et al., 2019). Neste último processo as OPCs têm a capacidade de migrar e se diferenciar em OLs maduros, a fim de remielinizar o local lesionado (Dimou et al., 2008). Estudos indicam que o bloqueio da oligodendrogênese acarreta na inibição de eventos que provêm a mielinização (Mckenzie et al., 2014). Anormalidades na mielinização ou em fatores que influenciam a mesma podem eventualmente levar à degradação funcional de importantes circuitos neurais, resultando em desorganizações, ineficiências cognitivas e comportamentais, os quais fazem parte da manifestação clínica da esquizofrenia (Mighdoll et al., 2015). Estudos *in vivo* e *in vitro* mostram que diversas drogas, como os antipsicóticos, podem modular a migração, proliferação e diferenciação das OPCs (Ren et al., 2013). Sendo assim, a modulação das OPCs e dos OLs maduros são essenciais para a compreensão de mecanismos relacionados à fisiopatologia e tratamento da esquizofrenia (de Almeida & Martins-de-Souza, 2018). Além disso, os mecanismos relacionados aos distúrbios de OLs, desmielinização e remielinização em transtornos neurológicos podem ser compreendidos a partir de modelos tóxicos de desmielinização (Bénardais et al., 2013). Diversas drogas são investigadas neste modelo para compreender seus potenciais efeitos nos processos de remielinização, neuroproteção e de indução da proliferação de OLs, como os canabinoides e antipsicóticos (Bartzokis, 2012; Zajicek & Apostu, 2011).

1.2 Modelo de estudo de desmielinização e remielinização

1.2.1 Modelo tóxico induzido por cuprizona

A mielinização dos axônios dos neurônios do SNC é essencial para a condução de sinais elétricos e manutenção da integridade do axônio (Taraboletti et al., 2017; Sachs et al., 2014). Desta forma, a desmielinização acarreta sérias consequência neurológicas, incluindo a redução da função motora e comprometimento nas habilidades cognitivas (Skaper, 2019). A compreensão dos mecanismos relacionados a mielinização e desmielinização, assim como anormalidades e mortes de OLs podem ser estudados através de modelos tóxicos induzidos por agentes farmacológicos, como a cuprizona, a qual pode ser

empregada tanto *in vivo* quanto *in vitro* (Bénardais et al., 2013; de Rosa et al., 2019; Xu et al., 2014; Xu et al., 2019).

As propriedades neurotóxicas da cuprizona induzem desmielinização em certas regiões do sistema nervoso de ratos, como no corpo caloso, hipocampo e pedúnculo cerebelar superior, sendo observado um declínio de mRNAs de proteínas relacionados a mielina (Acs et al., 2013a; Pasquini et al., 2007; Sachs et al., 2014). A priori, a sua toxicidade tem sido relacionada com distúrbios na homeostase de cobre no cérebro, devido a sua propriedade de quelação com este íon (Messori et al., 2007; Zatta et al., 2005). Por outro lado, estudos demonstram que a toxicidade desta droga ocorre devido à inibição das enzimas monoamina oxidase e citocromo c oxidase (Kesterson & Carlton, 1971; Venturini et al., 1973), à alterações nos complexos da cadeia transportadora de elétrons (Acs et al., 2013b) e a distúrbios na enzima superóxido dismutase de cobre e zinco (De & Subramanian, 1982), os quais acarretam em disfunções mitocondriais e na inibição da geração de energia, culminando na morte dos OLs (Moldovan et al., 2015; Taraboletti et al., 2017). Outros estudos indicam que durante a administração de cuprizona, há diminuição nos níveis de glutathione e consequentemente aumento no estresse oxidativo em OLs (Biancotti et al., 2008). Além disso, durante o uso da cuprizona é observado estresse do retículo endoplasmático, o qual é caracterizado pela proliferação do retículo endoplasmático e redução da síntese de proteínas (Praet et al., 2014). Desta forma, a depleção de energia, a indução de estresse oxidativo e de retículo endoplasmático afetam a viabilidade e proliferação de células em cultura, e consequentemente levam a uma falha no suporte metabólico da mielina (Benetti et al., 2010; Matsushima & Morell, 2001; Zendedel et al., 2013).

Ademais, um estudo demonstrou que a cuprizona pode se acumular intracelularmente, levando à morte de OLs da linhagem MO3.13 (Taraboletti et al., 2017). O estudo de Taraboletti et al. confirmou que há desregulação no metabolismo de NAD⁺ (dinucleotídeo de nicotinamida e adenina), na capacidade antioxidante da célula e no metabolismo da vitamina B6, em culturas celulares tratadas com cuprizona. Além disso, foi demonstrado que a cuprizona tem a capacidade de reduzir os níveis de MBP e CNP (2',3'-cyclic-nucleotide-3'-phosphodiesterase) em OLs (Xu et al., 2014). Considerando que uma das hipóteses para a toxicidade da cuprizona envolve alterações na geração de energia, e que o metabolismo de NAD⁺ encontra-se desregulado em células tratadas com essa droga, é

possível que a desregulação do metabolismo NAD⁺ contribua para a inibição da glicólise aeróbia e para depleção de energia, afetando os OLs maduros.

O modelo de desmielinização induzido por cuprizona é utilizado para compreender os mecanismos de desmielinização e remielinização, auxiliando potencialmente na identificação de novos alvos terapêuticos que possam melhorar a regeneração da mielina em certas doenças (Sachs et al., 2014). A remielinização *in vivo* se assemelha a um processo fisiológico de alta complexidade e regulação, seguindo quatro etapas consecutivas: a proliferação de células progenitoras de OLs, migração das células progenitoras para os axônios desmielinizados, diferenciação das OPCs e interação do OLs prematuro com o axônio (Zendedel et al., 2013). Neste contexto, diversas drogas são empregadas nos modelos de desmielinização com a finalidade de investigar seu potencial efeito na mielinização e nos OLs. Por outro lado, no modelo tóxico induzido por cuprizona *in vitro* é possível avaliar os mecanismos de diversas drogas em OLs em diferentes estágios de desenvolvimento, quanto aos seus potenciais efeitos em prevenir ou atenuar eventos relacionados às anormalidades induzidas nos OLs pela cuprizona e suas implicações para a mielinização.

1.2.2 Drogas potencialmente protetoras

1.2.2.1 Antipsicóticos

Estudos demonstram que a administração de antipsicóticos podem afetar de maneira distinta a expressão da mielina em adultos com esquizofrenia (Bartzokis et al. 2007; Bartzokis et al. 2009). Já em modelo de primatas foi demonstrado que a administração crônica de antipsicóticos de primeira ou segunda geração promovem aumento na densidade glial no córtex pré-frontal (Selemon et al., 1999). Desta forma, estes estudos suportam a hipótese de que administração desses fármacos pode aumentar a mielinização intracortical.

A utilização de haloperidol em modelo *in vivo* induz a mudança da expressão de genes relacionados a mielina e aos OLs, como MBP, PLP (proteína proteolípídica de mielina) e MAG (glicoproteína associada à mielina) (Narayan et al., 2007; Sugai et al., 2004). Já em cultura celular, há indícios que administração do haloperidol promove o aumento na proliferação e inibi a diferenciação de OPCs de rato, porém exerce efeito protetor em OLs contra a privação energética (Niu et al., 2010; Steiner et al., 2011). Por outro lado, diversos antipsicóticos de segunda geração são capazes de reduzir os níveis de espécies reativas de

oxigênio (ROS) e aumentar os níveis de glutatona e superóxido dismutase, levando a proteção contra a apoptose e à danos contra a mielina e OLs (Hendouei et al., 2018; Kriisa et al., 2016; Yan et al., 2014). Além disso, a quetiapina e a clozapina inibem efeitos induzidos pela cuprizona, a qual afeta diretamente a maturação e a diferenciação de OPCs *in vitro* (Xu et al., 2014). Já em modelo *in vivo* de cuprizona, a administração de quetiapina e clozapina induz a regeneração de OLs e o reparo da mielina após os eventos de desmielinização (Templeton et al., 2019; Zhang et al., 2012). Desta forma, diversos estudos indicam os potenciais efeitos dos antipsicóticos em induzir proteção contra danos na mielina e nos OLs. No entanto, diversas classes de drogas vêm sendo estudadas devido aos seus possíveis efeitos protetores, como por exemplo os canabinoides e a benzatropina.

1.2.2.2 Canabinoides

O interesse na modulação do sistema endocanabinoide aumentou desde a descoberta de compostos derivados da *Cannabis sativa*. O sistema endocanabinoide é composto por endocanabinoides (anandamida e 2-araquidonilglicerol), receptores de canabinoides do tipo 1 e tipo 2 (CB1 e CB2) e enzimas que são responsáveis pela síntese e degradação dos endocanabinoides (Khoury et al., 2019). Sendo assim, os endocanabinoides são importantes neuromoduladores responsáveis por controlar diversas funções no SNC (Lu & Mackie, 2016). Devido às propriedades lipofílicas dos endocanabinoides sua síntese ocorre nos neurônios pós-sinápticos, uma vez lançados por estes neurônios ligam-se a receptores dos neurônios pré-sinápticos do tipo canabinoides CB1 e CB2 ou não canabinoides, como os receptores GPR55 (*G protein-coupled receptor 55*), PPARs (*peroxisome proliferator activated nuclear receptors*) e TRPV1 (*transient receptor potential vanilloid-1 channel*) (Nevalainen & Irving, 2010; O'sullivan, 2016; Seabra et al., 2018; Zygmunt et al., 1999).

Embora os endocanabinoides anandamida (AEA, *N-arachidonoyl ethanolamine*) e 2-araquidonilglicerol (2-AG) tenham diferença significativa na seletividade dos receptores, ambos são produzidos em resposta ao aumento da concentração de Ca^{2+} no meio intracelular (Castillo et al., 2012). Resumidamente, a AEA é catalisada a partir de N-acil-fosfatidiletanolamina (NAPE) pela fosfolipase-D-específica de NAPE (NAPE-PLD) e a 2-AG é produzido de diacilglicerol (DAG) pela DAG lipase (DAGL) α ou β (Murataeva et al., 2014; Zou & Kumar, 2018). Nos neurônios a AEA é hidrolisada pela enzima amida hidrolase de ácidos graxos (FAAH) ou pela enzima N-acetil-etanolamina-hidrólise ácida amidase (NAAA), produzindo etanolamina e ácido araquidônico (Cravatt et al., 1996; Tsuboi et al.,

2005). Por outro lado, a 2-AG é degradada pelas lipases monoacilglicerol (MAGL) ou pelas serinas hidrolases α , β -hidrolase domínios proteínas 6 e 12 (ABHD6 e ABHD12) em glicerol e ácido araquidônico (figura 1) (Blankman et al., 2007). Estudos indicam que há uma comunicação mediada por endocanabinoides entre os neurônios e as células da glia, as quais também expressam receptores canabinoides e sintetizam endocanabinoides (de Almeida & Martins-de-Souza, 2018; Lyasov et al., 2018; Scheller & Kirchhof, 2016; Stella, 2009).

Diversos dados têm reforçado a participação do sistema endocanabinoide na fisiopatologia da esquizofrenia (Khoury et al., 2019). Neste contexto, diversos estudos têm indicado que pacientes com esse distúrbio apresentam níveis elevados de AEA (Potvin et al., 2020) e modificações nas expressões de receptores de canabinoides em diversas regiões cerebrais, como a diminuição da expressão receptor CB1 no córtex pré-frontal (Eggan et al., 2008; Muguruza et al., 2019) e diminuição da expressão do receptor CB2 periférico (Bioque et al., 2013). Recentemente foi demonstrado que os receptores CB2 podem estar relacionados com a cognição, psicose e comportamentos relacionados ao humor (ansiedade e depressão), os quais se manifestam em pacientes com esquizofrenia (Banaszkiewicz et al., 2020). Além dos citados acima, estudos indicam que a 2-AG e o bloqueio da enzima MALG estão relacionados com mecanismo de neuroproteção, devido aos seus efeitos anti-inflamatórios e pela redução da citotoxicidade em OLs e da desmielinização (Bernal-Chico et al., 2015; Chen et al., 2012; Panikashvili et al., 2001). Sendo assim, a modulação do sistema endocanabinoide pode ser um novo e promissor alvo farmacológico para tal distúrbio (Rohleder et al., 2016).

Figura 1. Representação do sistema endocanabinoide, adaptado de Seabra et al., 2018.

Os canabinoides surgiram como uma nova classe de drogas com potenciais efeitos sobre diversos distúrbios neurológicos e psiquiátricos. Já foram identificados mais de 70 canabinoides oriundos da planta *Cannabis sativa*, porém o Δ -9-tetrahydrocannabinol (THC) e o canabidiol (CBD) são os canabinoides mais abundantes (Khoury et al., 2019; Zajicek & Apostu, 2011). Diferente do THC, o CBD não desencadeia efeito psicomimético e ansiogênico (Campos et al., 2017; Khoury et al., 2019), exibindo, em contrapartida, um amplo espectro terapêutico, com propriedades ansiolíticas, antidepressivas e efeito neuroprotetor em uma gama de distúrbios psiquiátricos e neurodegenerativos. Sendo assim, diversos estudos clínicos têm apoiado a utilização do CBD em alguns transtornos, como na ansiedade, esquizofrenia, epilepsia e esclerose múltipla (Campos et al., 2017). Dessa forma, o efeito antipsicótico do CBD vem sendo investigado em diversos modelos de estudo (Rohleder et al., 2016). Estudos relatam que a administração de CBD contribui para a diminuição dos sintomas psicóticos em pacientes com esquizofrenia que não utilizaram antipsicóticos no período de três dias (Leweke et al., 2012). Também foi demonstrado que a administração de CBD em pacientes que respondem de modo parcial a medicação antipsicótica uma diminuição nos sintomas positivos e melhora no desempenho cognitivo (McGuire et al., 2018).

Além dos efeitos sobre o alívio dos sintomas, os canabinoides apresentam efeitos neuroprotetores (de Almeida & Martins-de-Souza, 2018; Zajicek & Apostu, 2011), possivelmente relacionados à efeitos anti-glutamatérgicos, bloqueio dos canais de cálcio, propriedades antioxidantes e ação anti-inflamatória (De Lago et al., 2009). Estudos demonstraram que tais componentes podem alterar a mielinização de células do SNC, e este efeito pode ser via receptores CB1 nos OLs (Tomas-Roig et al., 2016; Rodgers et al., 2013). Em modelo *in vivo* de esclerose múltipla, o CBD pode reduzir a apoptose dos OLs, os danos axonais, as respostas inflamatórias e aumentar a remielinização (Rahimi et al., 2015; Zajicek & Apostu, 2011). Já em modelo *in vitro* foi demonstrado que o CBD apresenta efeito protetor em OPCs contra o estresse oxidativo, pela diminuição de ROS, além de promover proteção contra o estresse de retículo endoplasmático (Mecha et al., 2012). Desta forma, o potencial efeito neuroprotetor do CBD é uma ferramenta farmacológica promissora para o tratamento dos OLs e melina acometidos na esquizofrenia e em outras desordens neurodegenerativas.

1.2.2.3 Benztropina

Além das citadas acima, outras drogas apresentam efeitos protetores para a mielina. A benztropina, por exemplo, é um antagonista de receptores muscarínico M1 e M3 e um agente anticolinérgico utilizado no tratamento da doença de Parkinson (Deshmukh et al., 2013; Kremer et al., 2015). Os receptores muscarínicos vem sendo propostos como um novo alvo terapêutico para a esquizofrenia, pois a ativação simultânea dos receptores de glutamato e muscarínicos têm a capacidade de reverter alterações relacionados a esquizofrenia em modelo animal (Cieślik et al., 2018).

Por outro lado, estudos indicam o potencial terapêutico desta droga na esclerose múltipla, devido a sua capacidade de promover a mielinização (Deshmukh et al., 2013; Kremer et al., 2015). Em modelo de desmielinização induzido por cuprizona, a benztropina contribui para o aumento da remielinização e diminui a porcentagem de desmielinização na substância branca em modelo de encefalomielite autoimune experimental (EAE) (Deshmukh et al., 2013; Thompson et al., 2018). Já em modelo de α -sinucleína foi demonstrado que a benztropina é capaz de reajustar processos relacionados a mielinização, como a biogênese de membrana e colesterol em OLs acometidos nesse modelo (Ettle et al., 2016). Em modelo *in vitro*, esta droga induz a diferenciação de OPCs de ratos e promove mielinização em co-cultura (Deshmukh et al., 2013), além de exercer efeitos antioxidantes em células neuronais, por meio do aumento de glutatona e pela redução de ROS (Cerles et al., 2019). Sendo assim, nos últimos anos diversos estudos vêm avaliando os efeitos protetores de diversos fármacos e seus potenciais efeitos terapêuticos. Diversas técnicas são utilizadas para a compreensão dos processos envolvidos em diferentes distúrbios neurológicos, como no caso da proteômica, uma tecnologia de suma importância para a avaliação de certas drogas nas células do SNC, assim como na identificação e compreensão de proteínas, vias e bases bioquímicas apresentadas em certos transtornos (Nascimento & Martins-de-Souza, 2015).

1.3 Proteômica

A grande complexidade do SNC vem sendo investigada pelas tecnologias denominadas de “ômicas” (Hosp & Mann, 2017). Neste contexto, a proteômica é uma importante ferramenta para a compreensão da base bioquímica de certos distúrbios cerebrais por meio da identificação de proteínas diferencialmente expressas, tanto no tecido cerebral,

quanto em modelos celulares. Através de metodologias proteômicas, também é possível identificar potenciais biomarcadores, auxiliando no melhoramento do diagnóstico e na escolha de um tratamento adequado (Nascimento & Martins-de-Souza, 2015). Sendo assim, ferramentas proteômicas como a espectrometria de massas (MS, *mass spectrometry*), podem ser utilizadas para elucidar os efeitos de drogas nas células do SNC, desvendando os caminhos de sinalização em distúrbios neurológicos.

Assim, através do uso de metodologias proteômicas, é possível investigar, de maneira quantitativa, a expressão global de proteínas ou grupos de proteínas (e suas modificações pós-traducionais), em um dado momento e local, visto que esses grupos podem mudar para cada tipo de célula e situação fisiológica. Ademais, constitui uma técnica de alto rendimento que fornece um perfil funcional do estado fisiológico atual, reflexo da complexa interação do gene com o ambiente. A importância dessas interações tem aumentado na pesquisa da esquizofrenia e outras doenças neurológicas (Nascimento & Martins-de-Souza, 2015).

1.3.1 Espectrometria de massas

Uma das primeiras ferramentas utilizadas em proteômica foi a eletroforese bidimensional (2D-PAGE), a fim de separar as proteínas de acordo com seu ponto isoelétrico por isoeletrofocalização e por sua massa através da migração em gel SDS-PAGE (Oliveira et al., 2014). A técnica de MS foi inserida combinada com 2D-PAGE para a identificação sistemática de polipeptídeos (Oliveira et al., 2014). A MS é uma técnica analítica utilizada para os estudos de proteínas e de outras biomoléculas na qual a razão massa molecular / carga (m/z) de moléculas ionizadas é mensurada, capaz de determinar a presença de proteínas, seus níveis e suas características estruturais, como sequências de aminoácidos e modificações pós-traducionais (Di Girolamo et al., 2013). Os espectrômetros de massas são compostos em três partes: uma fonte de ionização, um analisador de massas e um detector. A fonte de íons gera íons transferindo moléculas da fase condensada (líquida ou sólida) para a fase gasosa, ionizando as moléculas neste processo (carga positiva ou negativa) (Matthiesen & Bunkenborg, 2013). Os métodos mais comuns de ionização na proteômica são ionização por *electrospray* (ESI, *electrospray ionization*) e ionização dessorção a laser auxiliada por matriz (MALDI, *matrix-assisted laser desorption and ionization*) (Fenn et al., 1989; Karas & Hillenkamp, 1988). Após este processo de ionização, os íons são transferidos para o analisador de massas onde são separados de acordo com a razão m/z e finalmente detectados

por um detector (Domon & Aebersold, 2006; Matthiesen & Bunkenborg, 2013). Os espectrômetros mais novos também são capazes de separar íons através da sua mobilidade iônica, relativa à sua área transversal (Kanu et al., 2008).

A proteômica baseada em espectrometria de massas tem como objetivo identificar e quantificar proteínas e suas modificações pós-traducionais. Para fins de identificação essa técnica pode ser dividida em duas abordagens denominadas como *top-down* e *bottom-up* (ou *shotgun*) (Chait, 2006; Kelleher, 2004; Washburn et al., 2001). Na proteômica por *top-down*, as proteínas e os polipeptídeos intactos são submetidos às análises de MS/MS, a fim de identificar dados relacionados com a degradação de proteínas, isoformas e co-presença de modificações pós-traducionais (Padula et al., 2017). Já a proteômica por *bottom-up* utiliza uma mistura complexa de proteínas que são digeridas em peptídeos, normalmente por tripsina que cliva a sequência onde há resíduos de lisina e arginina, seguida de cromatografia líquida de alto desempenho acoplado ao espectrômetro de massas (Matthiesen & Bunkenborg, 2013). Na cromatografia líquida acoplada à espectrometria de massas (LC-MS), uma série de espectros de MS são adquiridos à medida que as moléculas eluem e por meio de um analisador de massas são gerados espectros MS/MS, onde as identidades de peptídeos podem ser calculadas por meio das razões m/z das transições dos peptídeos, as quais oferecem dados das sequências dos peptídeos. Por fim, a identificação de peptídeos é realizada por *softwares* de processamento de dados que utilizam espectros teóricos, produzidos a partir de bancos de dados de proteínas, a fim de comparar com os dados experimentais determinando as proteínas presentes com base nas sequências de peptídeos. Ao final, é gerada uma lista de proteínas identificadas e quantificadas que serão utilizadas para as análises *in silico*.

1.3.1.1 Técnicas de ionização

A formação de íons na fase gasosa é de extrema importância antes da mensuração de uma amostra por um analisador de massas. O avanço da espectrometria de massas de proteínas e peptídeos veio com a introdução de fontes de ionização por ESI e MALDI (Fenn et al., 1989; Karas & Hillenkamp, 1988). MALDI é um tipo de ionização por irradiação pulsada a laser, onde as amostras são misturadas a uma matriz que auxilia na sua ionização, por meio da transferência de energia da matriz energizada ao analito (Dass, 2007). Na técnica de ESI os analitos são dissolvidos em um solvente aquoso e bombeados para um capilar, onde existe um campo elétrico que acarreta na dispersão das amostras em aerossol e as ioniza,

por fim as moléculas carregadas repelem uma das outras até que ocorra um colapso na gota e a expulsão das moléculas em forma de íons (Dass, 2007).

1.3.1.2 Analisadores de massa

Atualmente na proteômica baseada em espectrometria de massas são utilizados cinco tipos de analisadores de massas, como quadrupolo (Q, *quadrupole mass filters*), TOF (*time of flight mass analyzers*), IT (*ion traps*), FT-ICR (*Fourier transform ion cyclotron resonance*) e Orbitrap. Nos analisadores de massa TOF, a relação m/z de um íon analítico é deduzida através do seu tempo de “vôo” no vácuo através de um tubo de comprimento conhecido (Andrews et al., 2011). Por outro lado, no analisador de quadrupolo os íons são separados de acordo com a sua m/z por meio de sua trajetória em campos elétricos oscilantes. Sendo assim, analisadores de massa Q-TOF são frequentemente constituídos por analisadores de massa quadrupolo (Q) seguidos de um analisador de massas TOF de alta resolução. Normalmente o Q é usado como guia de íons e para o resfriamento colisional dos íons que entram no instrumento, e em uma câmara de colisão realiza-se a fragmentação dos peptídeos e o TOF separa os íons de acordo com os valores de m/z (Domon & Aebersold, 2006; Matthiesen & Bunkenborg, 2013).

Ao final desses processos, o detector do espectrômetro de massas identifica e amplifica o sinal dos íons obtidos, convertendo os feixes de íons em sinais elétricos, sendo armazenados em espectros de massas, os quais podem ser analisados em programas computacionais como, MASCOT®, PLGS®, Sequest® e Progenesis®.

1.3.2 Synapt G2-Si

O espectrômetro utilizado para esse projeto de mestrado foi o Synapt G2-Si HDMS (Waters Corp, Milford, EUA). Este equipamento é equipado por uma fonte de ionização do tipo ESI e um aparelho do tipo Q-TOF, apresentando um quadrupolo e TOF como analisadores de massas, além de apresentar uma cela para a separação por mobilidade iônica (IMS) de alta eficiência (TriWave) subdividida em três câmaras: trap, câmara de mobilidade e transfer (figura 2). Primeiramente os íons são aprisionados no trap e injetados em períodos regulares na cela de mobilidade iônica, a qual irá separá-los em função *drift-time*, enquanto o transfer conduz os íons para o analisador TOF.

Com esse equipamento é possível fazer análises do tipo aquisição independente de dados (DIA, *data-independent acquisition*), envolvendo a fragmentação de peptídeos seguida da análise de sua composição de aminoácidos. O processo de fragmentação mais utilizado no MSe é a técnica de dissociação induzida por colisão (CID, *Collision Induced Dissociation*), a qual seleciona peptídeos em um quadrupolo e os acelera em uma região do espectrômetro de massas com um gás inerte (hélio, argônio ou nitrogênio) que acarreta na colisão entre os íons e as moléculas desse gás, transferindo a energia dessa colisão para as ligações presentes nos íons (Levin, 2011). Desta forma, o ciclo de aquisições de MS e MS/MS é adquirida ao longo da execução, os dados gerados m/z e o tempo de retenção para os íons precursores e fragmentos são extraídos para a identificação dos peptídeos e proteínas.

Figura 2. Esquema dos principais componentes do *Synapt G2-Si HDMS*, incluindo analisadores de massas e a cela de mobilidade iônica (trap, câmara de mobilidade e transfer), adaptado de *Waters Corporation*.

2. JUSTIFICATIVA

A esquizofrenia é uma desordem mental que afeta milhões de pessoas globalmente, privando os pacientes de uma vida normal. Diversos estudos, baseados em metodologias, incluindo a proteômica, apontam para anormalidades nos OLs e perda da mielina como fatores importantes na fisiopatologia da esquizofrenia. Neste contexto, modelos toxicológicos de desmielinização, como o induzido por cuprizona, são utilizados para compreender os mecanismos de desmielinização e remielinização, além de levar à identificação de novos alvos terapêuticos que auxiliam na regeneração da mielina em diversos distúrbios (Sachs et al., 2014). O modelo em questão pode ser aplicado tanto *in vitro*, quanto *in vivo* (Zendedel et al., 2013), contribuindo para o *cross-talk* de achados obtidos a partir de diversos estudos. Neste processo é especialmente importante utilizar culturas de OPCs, células neurais indiferenciadas e OLs em um estágio mais avançado de maturação, tanto para avaliar diferenciação, quanto efeitos inflamatórios, testar novos compostos químicos com potencial terapêutico, bem como desenvolver estratégias que ajudem a melhorar a remielinização (Torre-Fuentes et al., 2020). Ferramentas proteômicas, por sua vez, podem auxiliar na compreensão dos processos envolvidos no distúrbio neurológico citado acima, favorecendo a elucidação de bases bioquímicas, e identificação de proteínas e vias diferencialmente expressas, tanto nos distúrbios, quanto em seus tratamentos. Sendo assim, esta dissertação visou estudar os efeitos dos principais representantes de antipsicóticos (haloperidol e clozapina) e do CBD sobre os OLs MO3.13, por meio da utilização do modelo tóxico induzido por cuprizona. Como controle, investigamos também os efeitos da benztropina, conhecida protetora para estas células e indutora de mielinização em modelo *in vivo* e *in vitro*. Com isso, foram identificadas as proteínas e os processos biológicos afetados pelo tratamento com essas drogas. Consequentemente, o presente estudo contribuirá para o entendimento dos mecanismos bioquímicos e moleculares envolvidos na ação dessas drogas sobre os OLs.

3. OBJETIVOS

A presente dissertação teve como objetivo investigar os efeitos da benztropina, molécula indutora de mielinização e de diferenciação de OLs, e de drogas potencialmente protetoras, como os antipsicóticos (clozapina e haloperidol) e do canabidiol, sobre as alterações proteômicas induzidas pela cuprizona na linhagem celular de OLs humanos MO3.13. Desta forma, por meio da nano-cromatografia líquida acoplada à espectrometria de massas (*shotgun proteomics*) foram identificadas as proteínas e vias bioquímicas afetadas pelo tratamento com as drogas citadas anteriormente. No decorrer do projeto, foram delimitados os seguintes objetivos específicos:

- Cultivar a linhagem celular OLs humanos MO3.13;
- Estabelecer modelo de citotoxicidade induzida por cuprizona para esta linhagem;
- Realizar os co-tratamentos de tais células com cuprizona e canabidiol (componente da *C. sativa*), clozapina (antipsicótico de primeira geração), haloperidol (antipsicótico de segunda geração) ou benztropina;
- Extrair as proteínas das células tratadas e realizar a digestão do proteoma;
- Realizar análise proteômica por meio de nano-cromatografia acoplada à espectrometria de massas;
- Processar os dados e realizar análise de biologia de sistemas *in silico* dos dados obtidos.

Ao cumprir os objetivos propostos pretendemos colaborar com a hipótese que os antipsicóticos e o CBD podem ser potenciais drogas protetoras, como a benztropina, e ter a capacidade de prevenir ou atenuar eventos relacionados às anormalidades induzidas nos OLs pela cuprizona. Assim, contribuímos para entendimento de aspectos moleculares envolvidos nas ações destas drogas e seus potenciais efeitos protetores contra à danos gerados em OLs.

4. MATERIAIS E MÉTODOS

4.1 Cultura celular e tratamento

A linhagem de OLs humanos (MO3.13) é um híbrido que expressa características fenotípicas de OLs imaturos (Buntix et al., 2003; Iwata et al., 2013). Esta célula já tem sido utilizada em nosso laboratório e em estudos como modelo *in vitro* para compreender mecanismos relacionados à esquizofrenia (Brandão-Teles et al., 2019; Cassoli et al., 2016; Seabra et al., 2020). Os OLs foram cultivados em meio DMEM (Sigma-Aldrich), suplementado com 10% (v/v) de soro fetal bovino (Gibco), 1% de penicilina (100 U/ml) e estreptomicina (100 µg/mL) (Gibco), e mantidas em incubadora a 37°C em 5% CO₂, com renovação a cada dois dias, como descrito por nosso grupo anteriormente (Brandão-Teles et al., 2017; Iwata et al., 2013). As células foram utilizadas em diferentes passagens, e propagadas sem perder suas características iniciais, conforme as recomendações do fabricante. Para os ensaios de viabilidade celular, as células foram cultivadas na densidade 7.000 células/poço em placas de 96 poços (item 4.2) e nos ensaios de proteômica as células foram cultivadas na densidade de 115.000 células/poço em placas de 6 poços (item 4.3).

As soluções estoques de cuprizona (28,05mM; Sigma), haloperidol (53mM; Cristália), clozapina (25mM; Cristália) e canabidiol (25mM; USP Ribeirão Preto) foram preparadas por meio da solubilização em DMSO, com a concentração máxima de 0,042% de DMSO no meio de cultura. Já a benztropina (6mM; Merck) foi dissolvida em ddH₂O. Salina em DMSO (concentração final de 0,042% de DMSO) foram utilizadas como controle. Baseados nos resultados de MTT e em estudos anteriores, os OLs MO3.13 foram tratados com 10µM de cuprizona por 48 horas ou com 1µM de haloperidol, clozapina, canabidiol ou benztropina por 24 horas. Para os co-tratamentos, primeiramente foi realizado o insulto com cuprizona por 48 horas, e nas 24 horas finais foram adicionados haloperidol, clozapina, canabidiol ou benztropina no meio de cultura.

4.2 Ensaio de viabilidade celular (MTT)

Foi utilizado o método de viabilidade celular do MTT (tetrazólio) como parâmetro quantitativo de viabilidade celular. Resumidamente, o ensaio de viabilidade celular pelo método colorimétrico de redução de sais de tetrazólio (MTT- brometo de 3-[4,5-dimetil-tiazol-2-il]-2,5-difeniltetrazólio, Millipore) baseia-se na habilidade de células viáveis que converterem o sal tetrazólio em cristais de formazan (coloração púrpura). Assim, a

quantidade de cristais de formazan formada se compara diretamente com o número de células metabolicamente ativas (Liu et al., 1997). Faltando 1 hora para o fim do tratamento, as células foram incubadas com MTT (0,5 mg/mL) em DMEM não suplementado à 37 °C durante 2 horas. Após esse período de incubação, foram adicionados 100µL de etanol (100%) para diluição dos cristais de formazan e os valores de absorbância determinados no comprimento de onda de 570nm em um espectrofotômetro para placas. Para avaliação estatística os resultados foram expressos como média \pm erro padrão da média (E.P.M.). Para comparação de três ou mais médias foi utilizada análise de variância (ANOVA de uma via), seguido do pós-teste de Dunnett. O nível de significância para rejeição da hipótese de nulidade foi fixado em 5% ($\alpha < 0,05$).

4.3 Análise proteômica

4.3.1 Preparo de amostras

Para análise por espectrometria de massas, foram preparadas amostras proteicas de OLs MO3.13 tratados com 10µM de cuprizona por 48 horas, ou com 1µM de haloperidol, clozapina, canabidiol ou benztropina; e co-tratados com 10µM de cuprizona por 48 horas e com 1µM de haloperidol, clozapina, canabidiol ou benztropina nas últimas 24 horas do tratamento. Primeiramente as células foram coletadas com auxílio de *scraper* e PBS, (*phosphate-buffered saline*; concentração final 1x) e centrifugadas à 4°C e 14.000 g por 5 min. Logo em seguida, as amostras foram homogeneizadas em tampão de lise (Tris pH 6,8, 1 M; SDS 20%) junto com inibidor de protease (concentração final de 1x, Roche; Mannheim, Germany), sonicadas três vezes, aquecidas a 95°C por 5 minutos e aplicadas no gel de poliacrilamida. Após a corrida, os géis foram cortados e lavados com 50% acetonitrila (ACN) em 50mM de bicarbonato de amônio (Ambic) por 5 min até a remoção total do corante presente nos géis. Depois destes procedimentos foram adicionados 100µL de 10mM de dithiothreitol stock (15.4mg DTT em 10mL de 50mM de Ambic) e incubado por 30 minutos à 80°C. Ademais, as amostras foram incubadas com 100µL de 55mM de iodoacetamida stock (102mg IAA em 10mL de 50mM de Ambic) por 20 minutos, lavadas duas vezes com 200µL de ACN 100% por 10 minutos e colocadas no *Speed Vac* por 50 minutos.

Para a digestão das proteínas foi adicionado tripsina (1:50 enzima/substrato–2%) (Sigma-Aldrich / Promega) nas amostras durante o período de 16-18 horas a 37°C. Após este período, foram adicionados 50µL da solução Ambic 50mM, por 20 minutos, e o volume foi

transferido para um novo *eppendorf* já contendo 50µL da solução 50% ACN/5%AF (ácido fórmico). Nos tubos contendo os géis, foi adicionado 50µL da solução 50% ACN/5% AF por 20 minutos e então o conteúdo foi transferido para o tubo sem os géis. Depois dessas etapas, as amostras foram colocadas no *Speed Vac* até a secagem, e então armazenadas a -80°C.

4.3.2 Análise dos peptídeos por nanoLC-ESI MS/MS

As amostras foram centrifugadas à 4°C e 14.000 g por 5 minutos, a fim de transferir o sobrenadante para tubos *low-binding* e ressuspender em formiato de amônio pH 10. Em seguida as amostras foram injetadas em um sistema nanoAcquity UPLC M-Class (Waters Corporation, Milford, MA) acoplado ao espectrômetro Synapt G2-Si (Waters Corporation, Milford, MA). Primeiramente, as amostras foram fracionadas em cinco frações por meio de etapas descontínuas de ACN (11.4, 14.7, 17.4, 20.7 e 50%) antes da separação com gradientes de ACN contínuo de 7% a 40% (v/v) em colunas de C18 de fase reversa. Os dados MS e MS/MS foram obtidos de maneira dado-independente (DIA) utilizando UDMS^E após estabelecer o perfil do método de separação iônica para cada fração, usando DriftScape (version 2.9).

Os espectros MS/MS foram analisados pelo Progenesis® QI para proteômica (version 3.1) com Apex3D, peptideo 3D, e ion accounting informatics (Waters). As proteínas foram identificadas usando o banco de dado humano revisado (obtido em 11/2019) e quantificados usando o método Top3. Os seguintes parâmetros foram utilizados para identificar os peptídeos/proteínas: Digestão por tripsina com no máximo uma clivagem perdida; Massa máxima de 600 kDa; FDR menor que 1%; Pelo menos 2 fragmentos por peptídeo; Dois ou mais peptídeos por proteínas; Pelo menos 5 fragmentos por proteína; Pelo menos um peptídeo único por proteína; Mass error ≤ 20ppm. Na lista final de proteínas, foram consideradas para análise *in silico* aquelas que apresentarem pelo menos um peptídeo único e ANOVA < 0,05.

4.3.3 Análise *in silico*

As proteínas diferencialmente expressas por *shotgun* foram identificadas quanto aos seus processos biológicos e localizações celulares. Para compreender a rede de proteínas alteradas e sua importância para esquizofrenia, foram utilizados as seguintes ferramentas: Reactome (Fabregat et al., 2018), David bioinformatics database (Huang et al., 2009a; Huang et al., 2009b), Proteomaps (Liebermeister et al., 2014), Metascape (Zhou et al., 2019),

Cytoscape (Franz et al., 2016; Szklarczyk et al., 2017) e ClustVis (Metsalu & Vilo, 2015). Nesta etapa, foram considerados os *accessions* das proteínas diferencialmente reguladas, p-valor do teste anova ($p < 0,05$) e \log_2 FC (fold change), considerando a razão entre tratamento e controle, ou co-tratamento e cuprizona. As etapas experimentais descritas até aqui estão representadas na figura 3.

Figura 3. Representação das etapas experimentais, incluindo o tratamento e co-tratamento de OLs MO3.13 com cuprizona e/ou haloperidol (HAL), clozapina (CLZ), cannabidiol (CBD) e benztropina (BENZ), seguido das etapas de extração e digestão das proteínas,

quantificação dos peptídeos, análise de espectrometria de massas, processamento de dados e análise *in silico*.

REVIEW

published: 30 April 2020 doi: 10.3389/fpsyt.2020.00379

ABSTRACT

Oligodendrocytes are the glial cells responsible for the formation of the myelin sheath around axons. During neurodevelopment, oligodendrocytes undergo maturation and differentiation, and later remyelination in adulthood. Abnormalities in these processes have been associated with behavioral and cognitive dysfunctions and the development of various mental illnesses like schizophrenia. Several studies have implicated oligodendrocyte dysfunction and myelin abnormalities in the disorder, together with altered expression of myelin-related genes such as *Olig2*, *CNP*, and *NRG1*. However, the molecular mechanisms subjacent of these alterations remain elusive. Schizophrenia is a severe, chronic psychiatric disorder affecting more than 23 million individuals worldwide and its symptoms usually appear at the beginning of adulthood. Currently, the major therapeutic strategy for schizophrenia relies on the use of antipsychotics. Despite their widespread use, the effects of antipsychotics on glial cells, especially oligodendrocytes, remain unclear. Thus, in this review we highlight the current knowledge regarding oligodendrocyte dysfunction in schizophrenia, compiling data from (epi)genetic studies and up-to-date models to investigate the role of oligodendrocytes in the disorder. In addition, we examined potential targets currently investigated for the improvement of schizophrenia symptoms. Research in this area has been investigating potential beneficial compounds, including the D-amino acids D-aspartate and D-serine, that act as NMDA receptor agonists, modulating the glutamatergic signaling; the antioxidant N-acetylcysteine, a precursor in the synthesis of glutathione, protecting against the redox imbalance; as well as lithium, an inhibitor of glycogen synthase kinase 3b (GSK3b) signaling, contributing to oligodendrocyte survival and functioning. In conclusion, there is strong evidence linking oligodendrocyte dysfunction to the development of schizophrenia. Hence, a better understanding of oligodendrocyte differentiation, as well as the effects of antipsychotic medication in these cells, could have potential implications for understanding the development of schizophrenia and finding new targets for drug development.

Keywords: schizophrenia, oligodendrocyte, myelin, antipsychotic, glutamate

INTRODUCTION

Oligodendrocytes (OLs) are the neuroglial cells responsible for myelin sheath formation in the central nervous system (CNS). The life cycle of these cells consists of a series of coordinated and highly regulated processes, including migration, proliferation, maturation, and myelination of oligodendroglial cells, leading to adequate brain connectivity (1). In fact, the importance of OL development and myelination in neuronal signaling is well established, as evidenced by several behavioral and cognitive functions (2). Moreover, decreased myelination and OL alterations have been seen in patients with schizophrenia (3), associated with cognitive dysfunction (4). Recently, some studies have also proposed that OLs are more vulnerable to energy metabolism dysfunctions, oxidative damage, and other brain injuries (5, 6), leading to the impaired white matter integrity and brain dysconnectivity observed in schizophrenia (7). Nevertheless, the molecular mechanisms underlying these alterations remain elusive.

Schizophrenia is considered a multifactorial psychiatric disorder that affects more than 23 million individuals worldwide. This disorder is characterized by positive symptoms (delusions and hallucinations), negative symptoms (impaired motivation and social withdrawal), and cognitive impairment. Moreover, environmental and genetic factors, as well as neurodevelopmental dysfunction, play a role in the pathogenesis of schizophrenia (8, 9). The pathophysiology of the disorder includes molecular abnormalities in the nervous, immune, metabolic, and endocrine systems. Several hypotheses have been proposed to describe the etiology of schizophrenia, among which are the well-known dopaminergic and glutamatergic ones.

The dopaminergic hypothesis was developed during the 1970s in association with the discovery of antipsychotics' action on the blockade of D2 dopaminergic receptors (10). Over time, compelling evidence of altered dopaminergic transmission, involving D1 and D2 receptors, was shown in different brain areas linked to the development of positive symptoms and cognitive impairment in schizophrenia (11).

As for the glutamatergic hypothesis, antagonists of N-methyl-D-aspartate (NMDA) receptors mimic alterations and worsen symptoms observed in patients with

schizophrenia such as impaired memory, hallucinations, delusions, and agitation (12,13). This led to the postulation of a glutamatergic hypofunction in the disorder (14). Moreover, altered expressions of NMDA receptors and enzymes involved in glutamate metabolism have been found in patients with schizophrenia (15, 16).

Although there is evidence pointing toward these two aforementioned hypotheses, several lines of evidence also suggest the involvement of white matter abnormalities and neural dysconnectivity in the pathogenesis of schizophrenia (7). For instance, brain imaging and postmortem studies have demonstrated alterations in the myelination of cortical areas and white matter tracts, as well as a reduced number of OLs in patients with schizophrenia (3, 17). During neurodevelopment, dynamic and timely regulated changes in gray/white matter ratios appear to be crucial for adequate brain function (18, 19). During these processes, myelination occurs alongside neuronal development and ensures the brain's functional synchrony. Schizophrenia has been proposed to arise in part from faulty brain connectivity (20) and mounting evidence supports the notion of OL/myelination dysfunction as its underlying cause [reviewed in (21, 22)]. Despite the significant progress achieved in the comprehension of this multifactorial disorder in the past decades, the etiology of schizophrenia still remains unclear (23).

Currently, the main therapeutic strategy for the disorder relies on the use of antipsychotics. These medications mainly attenuate the positive symptoms, though atypical antipsychotics can induce slight improvements in cognitive and negative traits (24). Unfortunately, these same medications are also well known for their severe side effects, including metabolic syndrome and extrapyramidal effects, often leading to treatment discontinuation. In an attempt to change this situation, it is important to investigate the molecular mechanisms involved in antipsychotics' effects beyond neurons and the classical components of neurotransmission. OLs are one of the structures to be investigated to increase the understanding of the development of schizophrenia and find new targets for novel therapies.

In this review, we first describe the differentiation of OLs and myelination, followed by the pathways and signals involved in these processes. Secondly, we discuss how dysregulations in OL function may be linked with schizophrenia, as well as the main pathways and genes involved with OLs and this disorder. We also review current approaches being used to investigate the role of OL dysfunction in schizophrenia. Finally, we provide an

overview of the effects of antipsychotics on the proliferation and differentiation of OLs, and its potential for the discovery of novel therapeutic targets, suggesting new avenues for future research in the field.

OL DEVELOPMENT AND MYELINATION

The oligodendroglial cells are characterized as being cells that progressively mature from OL progenitor cells (OPCs) to myelinating cells through a series of coordinated and highly regulated programs of migration, proliferation, and differentiation, up to the point at which OLs become myelinating cells (1, 25). OPCs originate from neural stem cells (NSCs) that initially differentiate into neural progenitor cells (NPCs) in the subventricular zone (SVZ) (26). NPCs then give rise to OPCs, which migrate radially out of the SVZ to cortical and white matter areas (27, 28).

The maturation of OLs is controlled by transcription factors, and cell-extrinsic molecules, including small metabolic molecules, chemokines, growth factors, neurotransmitters, and hormones that act at defined time points during embryonic and postnatal development (29). Moreover, chromatin remodeling and epigenetic regulation, including methylation and histone modifications, are associated with OL development (30). During the initial stages of differentiation, histone deacetylation promotes chromatin compaction, ensuring that the transcription of non-OL genes is inhibited, followed by the induction of activators of OL cell fate (31, 32). In addition, DNA methylation plays a significant role in OPC expansion and regulates processes required for *de novo* myelination and remyelination, such as RNA splicing and protein synthesis (33, 34).

During maturation, cells committed to an OL lineage go through a series of specific phenotypic stages, including OPCs, pre-OLs, immature (or pre-myelinating) OLs and mature (or myelinating) OLs (1). These differentiation steps can be distinguished by migratory cell capacity, morphological complexity, and sequential expression of stage-specific markers in response to differentiation signals (1).

Initially, OPCs are proliferative cells that migrate and give rise to pre-OLs. These cells project multipolar processes and start to express OPC markers, such as O4, neuron-glial antigen 2 (NG2), A2B5, and OL lineage transcription factor 2 (Olig2) (35, 36). In turn, pre-

OLs differentiate into immature OLs, post-mitotic cells that present long ramified branches (36). Immature OLs begin to express 2', 3'-cyclic-nucleotide-3-phosphodiesterase (CNP) (37) and galactocerebroside C (GalC) while maintaining O4 expression and losing expression of NG2 and A2B5 markers (38). Throughout differentiation, OLs lose their ability to migrate and proliferate, acquiring a more complex morphology (39). Mature OLs extend axon-wrapping membranes and express myelin-associated proteins, among which are proteolipid protein (PLP), myelin basic protein (MBP), myelin OL glycoprotein (MOG), and myelin-associated glycoprotein (MAG) (40, 41).

Structurally, the myelin sheath is a multilayered, tightly packed membrane wrapped around selected nerve axons. It consists mainly of lipids (70%–80% dry weight—cholesterol and ethanolamine plasmalogen are the most predominant) and proteins (~20%–30% content) (42). The myelin sheath provides essential conditions for the conduction of saltatory nerve impulses, such as electrical resistance and reduced capacitance. Axonal myelination by OLs is a remarkable example of dynamic cell membrane specialization and remodeling, involving cytoskeletal rearrangements, along with cell–cell and cell–extracellular matrix interactions (43). Cytoplasmic compaction of the myelin lamellae provides the physical stability necessary for membrane wrapping, leading to cytoplasmic extrusion and adhesion of multiple layers of myelin (43). Therefore, during differentiation, the expression of negatively charged sialic acids by OLs is reduced, thereby decreasing electrostatic repulsion forces, which contributes to the adhesiveness and compaction of the myelin bilayer (44).

MBP and PLP are the two principal proteins present in compact myelin, increasing the adhesiveness of the myelin membrane, and contributing to myelin stability (44, 45). In contrast, CNP prevents myelin compaction through the rearrangement of the cytoskeleton (46). Thus, the interaction between MBP, PLP, and CNP is essential to avoid altered myelin compaction and to the maintenance of myelin stabilization (for review see (43)]. Besides those molecules, there are various biochemical pathways and signaling compounds released by other glial and neuronal cells that also contribute to the regulation of various stages of OPC differentiation and OL myelination, resulting in a complex and integrated network.

OL Development and Myelination: Signals and Pathways

In the brain, oligodendrogenesis and myelination require the activation of several signaling pathways, as well as transcription factors, noncoding RNAs, that act on the regulation of the different stages of OLs differentiation (47). Moreover, these processes are influenced by the interaction of astrocytes (48), microglia (49), and neurons with OLs and their precursors (50).

Regarding the role of glial cells in these interactions, astrocytes provide cholesterol precursors and nutrients for myelin sheath synthesis, in addition to chemokines and growth factors that influence OL survival, proliferation, migration, and maturation (48, 51). Similarly, microglia regulate oligodendrogenesis by releasing growth and attraction factors, including platelet-derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1) (52), and hepatocyte growth factor (HGF) (53). Moreover, neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) are known to guide axonal myelination (54, 55). Certain neurotransmitters and hormones can also stimulate oligodendroglial cells by mechanisms not yet completely understood (56).

Several pathways regulate OL differentiation and myelination in the CNS. The phosphatidylinositol-3-phosphate kinase (PI3K)/Akt/mTOR pathway, for example, regulates the initiation of myelination in the CNS through mTORC1 signaling (57). In conjunction, glycogen synthase kinase 3b (GSK3b) signaling regulates OL differentiation (58). Its inhibition induces OL proliferation and differentiation, as well as remyelination in mouse models of demyelination (58). Moreover, *in vivo* studies with mice overexpressing Akt also revealed an essential role of this pathway in inducing myelination rather than the proliferation of OLs (59).

Moreover, extracellular signal-regulated kinases-1 and -2 (ERK1/2), the downstream mediators of the mitogen-activated protein kinases (MAPKs) pathway, regulate myelin growth and maintain the integrity of myelinated axons (60). These MEK/ERK1/2-MAPK-mediated functions are largely independent of mTORC1 (61). Nonetheless, both pathways induce myelin sheath growth mediated by signaling responses involving mTORC1 (61). Therefore, PI3K/Akt/mTOR and MEK/ERK1/2-MAPK signaling pathways act both independently and in conjunction to temporally regulate OL differentiation and myelination (61). Disruptions in the finely tuned regulatory processes of OL development and myelination could result in white matter disturbances linked to the etiology of several mental

illnesses, including schizophrenia. These pathways are also associated with the treatment of this disorder, holding promising findings as potential targets for novel therapeutic strategies.

OLS AND MYELIN IMPAIRMENT IN SCHIZOPHRENIA

Disruptions during brain development caused by (epi)genetic and environmental factors can result in brain damage which could interfere in its ability to maintain normal communication across functional neural networks [for review see (62)]. Myelination is essential for adequate brain function and must occur alongside neuronal development and is only completed within the third decade of life. Disruptions in this process have been linked to the development of schizophrenia [for review see (63)].

The hypothesis that OLs play a major role in schizophrenia is corroborated by genome-wide expression analysis revealing altered expression of myelination-related genes in patients with schizophrenia and white matter pathologies that impair brain functional synchrony thereby resulting in schizophrenic symptoms (64–66).

In addition, structural changes have been reported in white matter tracts in the brains of patients with the disorder (67, 68). The anterior hippocampus plays an important role in the regulation of emotions and deficits in this area have been linked to schizophrenia. Studies have shown a decreased number of OLs in the hippocampus causing a disturbance in the neurocircuitry between the hippocampus and hypothalamus leading to cognitive deficits in patients with schizophrenia (69, 70). Furthermore, myelination deficits and dysfunctional synapses observed in the disorder can be correlated to the dysfunction of neuronal and glial function (71–73), along with cognitive impairment, including deficits in episodic and working memory (74) and in visual processing (75). Moreover, disruptions in OL integrity such as altered morphology and distribution (3), decreased density (76), and altered expression of myelination-related genes and proteins have been reported in patients with schizophrenia (71, 77, 78).

Epigenetics has also been suggested as an etiopathogenic factor for complex mental disorders, including schizophrenia (79). Aberrant epigenetic signatures, like hypermethylation, may be caused by well-known risk factors for schizophrenia during neurodevelopment such as drug abuse during pregnancy, in utero viral infections and hypoxia

(80, 81). Recent advances in sequencing technologies have allowed researchers to identify associations between schizophrenia and epigenetic modulations via DNA methylation and histone modifications (82–86). These have been shown to affect genes well-known for their role in OL lineage development (87), however, the majority of differential epigenetic signatures between OLs of control and schizophrenia brain samples have been found in non-coding regions (88).

Further insight into the pathology of schizophrenia and its connection with OL abnormalities has come from comparative proteomic analyses that reveal differentially expressed proteins and disturbances in biochemical pathways, including energy metabolism, oxidative stress and OL-related functions (78, 89). This is in line with an earlier brain imaging study that demonstrated decreased glucose metabolic rates in different thalamic nuclei in patients with schizophrenia (90). Nevertheless, schizophrenia pathophysiology also includes genetic factors. For this reason, several OL and myelin-related genes are being investigated in *postmortem*, *in vivo* and *in vitro* approaches to understand the contribution of genetic factors to OL development (73).

OL- and Myelin-Related Genes in Schizophrenia

Several (epi)genetic alterations, including risk variants and polymorphisms, have been demonstrated to play an important role in the etiology of schizophrenia (91, 92). Moreover, there are several promising candidate susceptibility genes associated with OL dysfunctions, such as Neuregulin 1 (NRG1)–ERBB4 signaling, Nogo-A/Nogo Receptor, Disrupted-in-schizophrenia 1 (DISC1), and other myelin-related genes (71, 93, 94). In an attempt to unravel the mechanisms involved with OL dysfunction in schizophrenia, OL- and myelin-related genes, as well as its regulatory signaling pathways are being investigated to understand how (epi)genetic and molecular changes lead to schizophrenia. Here we review the data available concerning those candidate myelin-related genes in the disorder.

NRG1–ERBB4 Signaling

NRG1 and its receptor ERBB4 are essential for neuronal, astroglial, and OL development, playing an important role in the survival and differentiation of these glial cells (95, 96). NRG1 is expressed at CNS synapses and activates neurotransmitter receptors, such

as the glutamatergic ones (94). This signaling pathway has been linked to schizophrenia as a potential genetic risk factor in genetic and *in vivo* studies (94, 97). NRG1 mutant mice have been shown to present altered behavior, including hyperactivity and a deficit in prepulse inhibition (PPI), which can be attenuated by treatment with the antipsychotic clozapine (CLZ) (98). The mice that were hypomorphic for NRG1 also had fewer functional NMDA receptors in the brain, a feature observed in schizophrenia patients (94). Moreover, NRG1 risk variants linked to schizophrenia have also been associated with reduced white matter density and integrity (99, 100). Regarding its functions in the CNS, the NRG1/ERBB4 signaling pathway operates in several aspects of neurodevelopment, including neural migration, gliogenesis, and modulation of neurotransmission [for review see (101)]. In addition, NRG1 is also involved with OL survival, migration, and myelination (96, 102, 103). Thus, the oligodendroglial association between this pathway and schizophrenia may be another potential alteration linking NRG1 to the development of the disorder (73).

Nogo-A and Nogo Receptor

The Nogo-A protein and its receptor (NGR) play an important role in the CNS through repairing processes, restricting axonal growth and plasticity (104, 105). This protein is extensively expressed in OLs, acting in the differentiation of these cells (106, 107). *In vivo*, mutant mice lacking Nogo-A exhibited impaired myelin synthesis and delayed differentiation (107). Moreover, Nogo-A knockout mice showed deficiencies in PPI and latent inhibition, as well as hyperactivity and other behavioral traits that resemble alterations observed in patients with schizophrenia (108). The induction of Nogo-A dysfunction in adult mice failed to reproduce the alterations observed in the mutant mice (108). Hence, Nogo-A dysfunction during neurodevelopment may affect neuronal and glial differentiation (107, 109). Altered expression and polymorphisms of the RTN4 (Reticulon 4) gene, which codes for Nogo-A, have been associated with psychiatric disorders like schizophrenia (110). Thus, alterations involving Nogo-A, NGR and other associated pathways, could contribute to some abnormalities observed in the disorder, such as abnormal neuronal organization and connectivity. Further research is needed to help underline the molecular mechanisms linking Nogo-A and NGR to the pathophysiology of schizophrenia [for review see (111)].

Disrupted-in-Schizophrenia 1

DISC1 is a gene disrupted by a chromosomal translocation that has been linked to psychiatric conditions, including schizophrenia, but its association with the disorder remains controversial (93, 112). Studies using *in vivo* models with mutant, truncated DISC1 observed altered OL differentiation and proliferation and alterations in OPC marker levels (113, 114). Investigation of altered gene expression profiles linked to DISC1 has found an association with altered levels of OL markers, such as CNP, MAG, and PLP (114), which contribute to altered white matter functioning and integrity (115). Moreover, postmortem studies have revealed an increased expression of DISC1 protein in OLs in frontal-parietal white matter region in paranoid schizophrenia (116). Thus, DISC1-related polymorphisms may contribute to neurodevelopmental alterations, as well as changes in white matter integrity, participating in the etiology of schizophrenia (115).

Olig2

Olig2 encodes for a transcription factor essential for several aspects of neurodevelopment, including oligodendrogenesis, the formation of motor neurons, and OL differentiation, especially in the early stages of OPC differentiation (117, 118). In postmortem studies, mRNA levels of Olig2 have been found reduced in patients with schizophrenia compared to healthy individuals (71, 119). Studies have described the expression of Olig genes in white matter and during remyelination in a demyelination model (120, 121). Other genes involved with myelination have been correlated with Olig2 expression, including ERBB4 and CNP, which may indicate potential shared pathways and interactions among these genes (122).

Other Myelin-Related Genes

Aside from the genes discussed above, there are other genes that have been found to be differentially expressed in patients with schizophrenia which are related to OLs. MAG, CNP, PLP1, and MBP were found reduced in mRNA samples from patients with schizophrenia in postmortem studies (71, 123). Genetic and neuroimaging data have shown that the MAG, Olig2, and CNP genes can influence white matter integrity and cognitive performance in schizophrenia patients (124). As previously mentioned, CNP is a marker for OLs during neurodevelopment and is also maintained in mature OLs (38, 125). It has been proposed that the inhibition of CNP in OLs can affect an essential glial trophic support mechanism of axons (126).

Another genetic study evaluated the mRNA expression of Quaking I (QKI), finding two splice variants to be downregulated in patients with schizophrenia (127, 128). QKI is an RNA-binding protein important for the development of glial cells and myelin synthesis (129). In an *in vivo* model, mutant mice (qkv) with a deletion in the 5' regulatory region of the QKI gene presented severe demyelination, altered myelin structure, and reduced lipid content (130, 131). This gene is involved in the regulation of other genes essential for OL differentiation, such as PLP1, MAG, and MBP (132, 133).

Moreover, the Fasciculation and Elongation Protein Zeta-1 (FEZ1) is another myelin-related gene associated with risk for schizophrenia. FEZ1 is a gene involved with OL differentiation and it is known to interact with other schizophrenia-related genes, including DISC1 and QKI, mentioned above (134). FEZ1 has also been found reduced in the hippocampus of patients with schizophrenia and its expression has been associated with disrupted regulation of transcription factors and altered (epi) genetic regulation, including histone acetylation and chromatin remodeling (134, 135).

Changes in (epi)genetic regulation in myelin-related genes have been associated with impaired OL function and development (30). Inhibition of methylation reduces the number of OLs, evidencing the vulnerability of these glial cells to (epi) genetic alterations (136). Moreover, methylome analysis of different cell types isolated from brain tissue of patients with schizophrenia and controls revealed altered methylation associated with OLs (88). For instance, SOX10, a well-known marker of OL development has been shown to be hypermethylated in schizophrenia patients (87); this methylation status may be correlated to its downregulation and OL dysfunction in the disorder.

Therefore, the (epi)genetic components partially explain the etiology of schizophrenia and also support the notion that oligodendroglial abnormalities are among the primary deficits in the disorder (73). However, the individual and collective roles of all these genes remain unknown, making it still somewhat controversial in relation to schizophrenia. Environmental factors have also been associated with the etiology of the disorder, including complications during pregnancy and prenatal maternal infections (137, 138). These scenarios may lead to hypoxic damage and an inflammatory state, which have been linked to gray and white matter dysfunctions (139, 140).

Together, genetic susceptibility and certain environmental conditions may contribute to the development of (epi)genetic dysregulations. Hence, the investigation of the molecular mechanisms behind these different risk factors is essential for the comprehension of the etiology of schizophrenia. Data provided by brain imaging studies, genetic (71, 141) and postmortem studies (142, 143), in addition to animal models (94, 98) have been crucial to unravel these mechanisms as well as to understand the role of OL dysfunction in schizophrenia.

MODELS OF OL AND MYELIN-RELATED DISORDERS

To better understand the molecular changes in OLs and myelination dysfunctions, studies have used different *in vitro* and *in vivo* models to investigate abnormalities observed in OPC differentiation and myelination processes. Aiming to bring together the interactions between genetic and environmental factors, experiments using induced pluripotent stem cells (iPSCs) derived from patients with schizophrenia are being developed to generate OPCs and mature OLs. These tools can help us comprehend the association between OL abnormalities and the development of the disorder as well as aid in screenings for novel therapeutics (144, 145). In addition to iPSCs, mouse primary OPC cultures and oligodendroglial cell lines (MO3.13 and HOG) have also been used to understand the biological processes underlying OL differentiation into myelinating OLs (146–148).

Human-Induced Pluripotent Stem Cells-Derived OPCs

For neurobiological studies related to the CNS, patient-derived human iPSCs (hiPSCs) are able to be reprogrammed into neuronal and glial cell types, including OPCs and OLs, offering potential tools to elucidate the molecular and cellular mechanisms behind the etiology of schizophrenia (149). One of the main advantages of iPSCs is the conservation of the original genotype and endophenotype from schizophrenia patients (150, 151). Thus far, studies of psychiatric disorders using patient-derived iPSCs have focused on neuronal differentiation (152–154) and have demonstrated decreased neuronal connectivity, increased oxidative stress and mitochondrial dysfunction and, consequently, an impairment in NPC differentiation and neuronal maturation (151, 155).

Recently, studies have started looking toward OPCs derived from iPSCs in neurodegenerative and psychiatric diseases to understand specific aspects of the myelination process and to investigate how dysfunctional neuron–OL interactions manifest in schizophrenia (146, 156). However, currently available protocols for the differentiation of iPSCs into OPC are still very limited and are not able to induce differentiation into a mature myelinating OL. Wang et al. (2013) developed a protocol to produce myelinogenic OLs from skin-derived hiPSCs and showed the potential therapeutic of hiPSC-derived OPCs as a treatment for disorders of myelin loss (157). In the context of schizophrenia, a protocol used to generate hiPSC-derived OPCs from patients confirmed that OL dysfunction and anomalies were similar to the alterations in white matter integrity observed in magnetic resonance imaging studies from patients with schizophrenia. Thus, both models confirm OL abnormalities in schizophrenia, linking OL dysfunction with a decreased number of OPCs (145).

Primary OPC Culture and Oligodendroglial Cells Lines

Primary glial cell cultures from mice and rats are the most common and well-established *in vitro* model used for the study of diseases that affect the CNS and allow the study of OPC differentiation and OL function at the cellular and molecular levels (158, 159). One advantage of primary OPC culture is the availability of protocols for the isolation of OLs, microglia and astrocytes from mixed glial cultures. Such protocols are an economical, simple and reproducible way to obtain oligodendroglial cells with high purity and high efficiency, besides requiring a reduced number of animals (160, 161).

Following the pathway of practical, fast and economical *in vitro* models, the oligodendroglial cells lines MO3.13 and HOG have also been used to analyze OL differentiation and abnormalities (162). MO3.13 is an immortal human-human hybrid cell line, created by fusing rhabdomyosarcoma cells with adult OLs (163). The HOG cell line is directly derived from a human glioma that expresses OL markers MBP and CNPase but does not express glial markers, such as GFAP and glutamine synthase (164). MO3.13, however, expresses GFAP and also exhibits GalC and CNPase immunoreactivity (163). Upon differentiation, MO3.13 cells express MBP and PLP, which are markers for mature OLs (163, 165). Both cell lines have been employed as models to study the cellular neurobiology in OL-linked diseases, such as multiple sclerosis (166) and schizophrenia (5, 167). Unfortunately, protocols to differentiate HOG and MO3.13 into mature OLs vary greatly and these cell lines

do not reach a myelinating state, which jeopardizes a more comprehensive study of myelination process using these models (148).

To study the neurobiological alterations in schizophrenia, including the glutamatergic dysfunction in OL, the MO3.13 cell line was treated with MK-801, a glutamatergic NMDA receptor antagonist that mimics the hypofunction in glutamatergic signaling seen in schizophrenia patients (165). The results exhibit differentially expressed proteins related to energy metabolism and glycolysis (5), including proteins previously associated with schizophrenia (165). Moreover, MK-801-treated OLs present more severe alterations compared to neuronal and astrocyte cell lineages, causing OLs to exhibit increased vulnerability to NMDA and glutamatergic dysfunction (5). Given the OLs' high energy demand to promote axon myelination, these metabolic disturbances could lead to white matter dysfunction and, consequently, altered neuronal connectivity, thereby playing a major role in the etiology of schizophrenia (168, 169).

Despite partially representing disturbances observed in schizophrenia and comprising critical tools in understanding OLs and white matter dysfunctions in schizophrenia, the use of isolated OL cell line cultures cannot reproduce complex physiological processes such as the communication between OLs and neurons, which is an essential factor for *in vivo* myelination and remyelination. In this context, the development of neuronal and glial co-culture systems, brain organoids, and organotypic slice cultures come much closer to the biological conditions present in a physiological environment (73, 151) Furthermore, a more robust way to study cell–cell interactions in the pathogenesis of schizophrenia and to better understand how OL–neuron interactions contribute to abnormal myelination, is by using the *in vivo* models of demyelinating diseases and remyelination processes.

***In Vivo* and *In Vitro* Strategies Using Cuprizone-Induced Demyelination**

The cuprizone (CPZ; bis-cyclohexanone oxaldihydrazone) model is a common animal model used to investigate demyelination-associated diseases such as multiple sclerosis and schizophrenia (170). CPZ is a copper chelator that impairs the activity of copper enzymes (cytochrome oxidase and monoamine oxidases), developing reversible, region-specific OL loss and demyelination, as well as stimulating microgliosis and astrogliosis (171–173). The CPZ hypothesis proposes that perturbation in energy metabolism contributes

to OL apoptosis and induces demyelination [for review see (170)]. Furthermore, CPZ reduces the expression of myelin-related genes and proteins, such as MBP, MOG, PLP, and CNP in animals' corpus callosum (174), consequently inducing brain demyelination, myelin disruption, and OL loss (170, 174, 175). This animal model manifests symptoms similar to those observed in schizophrenia patients, such as deficits in working memory (176, 177) and in PPI of the acoustic startle response, less social interaction, and higher dopamine in the prefrontal cortex (PFC) (175), showing that OL dysfunction and abnormal myelination triggers schizophrenia-like symptoms.

The main CPZ-toxic target are mature OLs. CPZ also has a toxic effect in OLs cultured cells, causing a direct disruption of OL function. For instance, Taraboletti (2017) showed that CPZ induces cell death in the MO3.13 cell line through changes in oligodendroglial energy metabolism (178). CPZ is not able to exert toxic effects on microglia, astrocytes, and SH-SY5Y cells, showing a selective effect in OLs. Moreover, CPZ inhibits the differentiation and maturation of cultured OPCs and decreases the levels of CNP and MBP in mature OLs (179). These results highlight the selective demyelination induced by CPZ *in vivo*, showing that the CPZ model may be a potential experimental tool for assessing molecules related to demyelination and remyelination (170, 180).

Currently, it is unknown whether OL dysfunction consists of a primary or a secondary cause of neuronal and synaptic abnormalities in schizophrenia. Thus, it is important to study cell–cell interactions in the schizophrenia pathologic process. All the models described above partially represent OL and myelination disturbances observed in schizophrenia, comprising critical tools in understanding OLs and white matter dysfunction in this disorder. However, schizophrenia is a multifactorial psychiatric disorder, involving environmental and genetic factors, as well as neurodevelopmental dysfunction (8, 9). For this reason, developing a model that links genetic and environmental elements with cellular and molecular alterations associated with positive and negative symptoms, and cognitive impairment is still a challenge.

Molecular pathogenesis research using iPSC-related technologies, such as three-dimensional (3D) culture models and organoids, offers new insight to recapitulate the complexity of the human CNS. Novel findings derived from these models, associated with clinical phenotype in postmortem, *in vivo*, *in vitro* approaches and findings from brain

magnetic resonance imaging and genomic studies, will be increasingly important for a better understanding of the processes involving OL dysfunction in schizophrenia (151).

ANTIPSYCHOTICS AND OLS

Currently, the major therapeutic strategy for schizophrenia relies on the use of antipsychotic drugs. Antipsychotics are high affinity antagonists of dopamine D2 receptors and are categorized into two classes: typical, or first-generation and atypical, or second generation. The typical antipsychotics, such as haloperidol (HAL), act mainly through dopamine D2 antagonism, thereby improving positive symptoms (10, 181). These antipsychotics induce severe extrapyramidal side effects and have a high incidence of nonresponders (182). In contrast, atypical antipsychotics, such as CLZ, inhibit dopamine D2 as well as serotonergic receptors (especially 5-HT_{2A} and 5-HT_{2C}) (183). They attenuate principally positive symptoms and induce fewer neurological side effects; however, they can lead to metabolic disturbances (184).

Antipsychotics were found to target OL development, reinforcing the role of OLS in the pathophysiology and treatment of schizophrenia (185). *In vitro* and *in vivo* studies have been investigating the effects of atypical and typical antipsychotics on the proliferation and differentiation of glial cells (185–187). The results obtained so far remain controversial; while one study reports that the typical antipsychotic HAL promotes proliferation but not the differentiation of OLS (188) another one confirmed HAL inhibition of OL differentiation but found no effects on OL proliferation (186, 188). Regarding the atypical antipsychotics, olanzapine and quetiapine (QUE) induce OL proliferation, however, only QUE promotes OL differentiation, through ERK1/2 signaling and increases CNP and MBP levels (176).

Recent studies have found that the atypical antipsychotic QUE, administered both before or after CPZ-mediated demyelination, significantly enhances OL regeneration and myelin repair by accelerating the maturation of OPCs (187, 189). This acceleration promotes the survival of OLS, linked to a downregulation of the transcription factor Olig2 in the process of cell maturation (189). Regarding behavioral changes, QUE treatment during the remyelination period improves spatial working memory (189) and cognitive impairments (176) and reverses the deficit in PPI of the acoustic startle response in CPZ-treated mice (175, 177). Antipsychotic treatment (CLZ, QUE, and HAL) in the CPZ model reversed higher

dopamine levels in the PFC and lowered spontaneous alternations in Y-maze tests induced by CPZ (175). The study also revealed that, in mice treated with CPZ, the white matter damage in the PFC was reduced after treatment with CLZ or HAL. Moreover, in the caudate–putamen and hippocampus white matter loss was only attenuated by CLZ and QUE (190).

Moreover, in a mouse model of social isolation, animals treated with QUE presented reduced myelin deficits and increased histone methylation in OLs, besides an improvement in social interactions (191). QUE has also been associated with increased methylation of risk factor genes implicated with schizophrenia, providing evidence that epigenetic regulation may be involved in the mechanisms of action of this antipsychotic (192).

Other antipsychotics have also been associated with epigenetic modifications. *In vivo*, OLA induced altered methylation of genes involved with dopaminergic signaling in the hippocampus and cerebellum (193); CLZ was able to reverse epigenetic alterations induced by phencyclidine treatment in mice, improving cognitive dysfunction, memory recognition, and social deficit (194).

Regarding biochemical pathways, it has been shown that antipsychotic effects are associated with cortical and gray/white matter intensity and with lipid metabolism alterations (195, 196). CLZ and HAL can alter OL glucose metabolism, which is deregulated and correlated with abnormal behavior and cognition in schizophrenia patients (196). Moreover, these drugs are able to stimulate the synthesis of cholesterol and fatty acids in glial cells through regulation of gene expression mediated by the sterol regulatory element-binding proteins SREBP-1 and SREBP-2 (197). Glia-derived cholesterol is essential for the formation of myelin and synapses in the CNS (198). Cholesterol metabolism has been implicated in the regulation of many processes, including myelin membrane growth, axon wrapping, and synapse formation. Thus, cholesterol and myelin synthesis are essential for brain physiological homeostasis (199).

Moreover, reduced Akt signaling has been found in the frontal cortex of postmortem brain tissue from patients with schizophrenia (200, 201). *In vivo* animal models modulating Akt signaling have also exhibited schizophrenia-like behaviors and abnormalities (202, 203). Another *in vivo* study investigated the effect of HAL on Akt signaling, finding increased phosphorylation of Akt as a potential protective mechanism of the medication

(200). PI3K/AKT/mTOR signaling is a well established pathway related to several biological processes, including protein synthesis and cell growth, also playing an important role in OL survival (59). Proteomic analyses of the human immature oligodendroglial cell line MO3.13 found altered proteins associated with the mTOR signaling pathway after treatment with atypical (risperidone and QUE) and typical antipsychotics (chlorpromazine and HAL) (204). According to this study, these medications resulted in different protein expression levels, revealing potentially distinct effects of those drugs on OLs.

As such, upstream and downstream processes linked with PI3K/Akt/mTOR signaling may not only influence OL functioning but may also be associated with the molecular mechanisms of antipsychotics. One example is Akt and GSK3b signaling, found to be mediated by cyclin-dependent kinase 5 (Cdk5) (205); in this study, the *in vivo* model for Cdk5 knockout resulted in impaired remyelination and reduced phosphorylation levels of Akt and GSK3b, indicating the potential role of Cdk5 in the regulation of both pathways. Reduced phosphorylation of GSK3b inhibits differentiation and myelination of OLs (58). As a result, GSK3b inhibitors are being investigated as potential targets for remyelinating drugs such as lithium, discussed in the following section.

In summary, aberrations in OL development and myelin contribute to the pathogenesis of schizophrenia and drugs that reverse abnormal OL phenotypes may be a promising treatment strategy. OL development is a target of some antipsychotics (185) and understanding the effects of antipsychotics on OLs reinforces the need for future therapeutic intervention studies.

NOVEL POTENTIAL THERAPEUTIC TARGETS

In this review, OL maturation and function in the CNS have already been discussed, detailing how these cells may be involved in the pathophysiology of schizophrenia. From postmortem brain studies to *in vivo* and *in vitro* models, several approaches were reviewed, all of which have been used to investigate OL dysfunctions in this psychiatric disorder.

Data from these different strategies exhibit alterations in myelin-related genes in patients with schizophrenia. Further investigation of these candidate genes may contribute to

the search for possible targets for drug development. Given the association of white matter dysfunction with brain dysconnectivity and the development of positive, negative, and cognitive symptoms observed in schizophrenia (206–208), the investigation of potential promyelination agents and other protective substances during myelination in the CNS could provide strategies to prevent the damage caused by altered myelination and other OL dysfunctions.

As for typical and atypical antipsychotics, since they are the main therapeutic strategy currently used for the treatment of schizophrenia, a better understanding of their effects on the proliferation and differentiation of OLs is crucial. Their molecular mechanisms and effects on the white matter remain elusive and more data are necessary to determine any protective and negative effects of those drugs after short- and long-term treatment, especially related to white matter integrity.

In regard to glutamatergic dysfunction, altered signaling and receptors dysfunction have been described in schizophrenia (14). Glial cells are especially vulnerable to glutamate excitotoxicity (209), resulting in impaired OL functioning and white matter lesions (210). Therefore, the investigation of compounds able to prevent this excitotoxicity could provide protective effects, especially to attenuate white matter injury. One example is memantine, a non-competitive NMDA antagonist with a low binding affinity that acts by partially blocking this receptor, preventing glutamate toxicity (211, 212).

Other NMDA modulatory compounds include NMDA receptor agonists, such as D-amino acids: D-aspartate and D-serine. D-aspartate also acts as an NMDAR precursor and is essential in several processes in the CNS, including cognitive function (213, 214). Regarding its role in OLs, D-aspartate contributes to remyelination and is also associated with OL maturation and differentiation (215). D-serine is an endogenous ligand for the glycine site of NMDA receptors. Together with glutamatergic signaling, D-serine was found to contribute to the induction and maintenance of long-term potentiation in synaptic plasticity (216). Clinical trials showed that the administration of D-serine alleviated positive, cognitive, and negative symptoms in schizophrenia patients (217).

Given the negative regulation of GSK3b signaling in OLs, GSK3b inhibitors also present promising results for OL differentiation and survival (58). Lithium is one such inhibitor and is a well-known mood stabilizer employed in bipolar disorder treatment. It

exhibits neuroprotective properties, promoting increased expression of myelin-related genes and OL remyelination (218, 219). Lithium was also found to improve symptoms involving emotional withdrawal, motor activity, disorganized thoughts, and positive symptoms in patients with schizophrenia (220).

Altered energy metabolism has also been reported in schizophrenia, leading to an impaired redox balance (78). OPCs are more sensitive to oxidative stress and have lower glutathione (GSH) levels compared to other cells like neurons and astrocytes (168). The tripeptide GSH is an essential intracellular antioxidant also found at reduced levels in patients with schizophrenia (221). It has been suggested that antioxidants such as N-acetylcysteine, which acts as a precursor of cysteine in GSH synthesis, could be an adjunctive strategy in the treatment of psychiatric disorders (222).

Another signaling process that can become a target for drug discovery studies in OLs is the endocannabinoid system. This system acts in the survival, proliferation, migration, and differentiation of OLs (223). OPCs are known to produce the endocannabinoid arachidonoylglycerol (2-AG), consequently stimulating the ERK signaling pathway, inducing OL differentiation and MBP production (224). Cannabidiol (CBD) is a phytocannabinoid that has presented beneficial effects on OLs, protecting OPCs against inflammation-induced damage and oxidative and endoplasmic reticulum stress (225). All potential targets discussed above are summarized in **Figure 1**.

CONCLUSION

Due to the high complexity of and interaction between, (epi)genetic and environmental factors linked to the development of schizophrenia symptoms, several pathways, along with white and gray matter dysfunction, have been implicated in the disorder. To date, investigations have focused on neuronal cells and, more recently, some studies have been shifting their focus toward the role of glial cells in schizophrenia. Combined data from different *in vivo* and *in vitro* models, as well as brain imaging and postmortem studies, provide evidence for white matter dysfunction and dysconnectivity, both observed in schizophrenia. However, the molecular mechanisms underlying these alterations remain unclear.

Thus, continued research in the field could provide further knowledge regarding the role of OLs in the pathophysiology of the disorder, as well as the effects of antipsychotic medication on these cells. This, in turn, would contribute to the discovery of novel targets and the development of new approaches targeting cognitive and negative symptoms, designing adjunctive treatments alongside antipsychotics.

Figure 1. Schematic representation of the main signaling processes and potential novel treatment targets involved with oligodendrocyte dysfunction in schizophrenia. Antipsychotics acting via inhibition of D2 and 5-HT2A receptors are the main therapeutic strategy currently used in schizophrenia treatment. D-amino acids and memantine are shown here as potential targets aiming for improvements in the glutamatergic signaling dysfunction. Endocannabinoids and the GSK3b inhibitor, lithium, contribute to the MEK/ERK1/2-MAPK and PI3K/Akt/mTOR signaling pathways, which are important for oligodendrocyte proliferation and differentiation. Moreover, aiming to attenuate oxidative damage, antioxidants such as N-acetylcysteine may consist of potential therapeutic agents.

NOMENCLATURE

BDNF, brain-derived neurotrophic factor; CBD, cannabidiol; CLZ, clozapine; CNP, 2', 3' -cyclic-nucleotide- 3 - phosphodiesterase; CNS, central nervous system; CPZ, cuprizone;

DISC1, disrupted-in-schizophrenia 1; ERK1/2, signal-regulated kinases-1 and -2; GalC, galactocerebroside C; GSH, glutathione; GSK3b, glycogen synthase kinase 3b; HAL, haloperidol; IGF-1, insulin-like growth factor 1; MAG, myelin associated glycoprotein; MAPKs, mitogen-activated protein kinases; MBP, myelin basic protein; MOG, myelin oligodendrocyte glycoprotein; mTOR, mammalian target of rapamycin; NG2, neuron-glia antigen 2; NGR, Nogo Receptor; NGF, nerve growth factor; NMDA, N-methyl-D-aspartate; NPC, neural progenitor cells; NRG1, Neuregulin 1; NSC, neural stem cells; Olig2, oligodendrocyte lineage transcription factor 2; OL, oligodendrocyte; OPCs, oligodendrocyte progenitor cells; PFC, prefrontal cortex; PI3K, phosphoinositide 3-kinase; PLP, proteolipid protein; PPI, prepulse inhibition; QKI, Quaking I; QUE, quetiapine; Rtn4, Reticulon 4; SVZ, subventricular zone.

AUTHOR CONTRIBUTIONS

DG-J conceived the study, designed, and wrote the manuscript. AA helped with data interpretation and manuscript revision. GS and AF conceived the study and assisted with the manuscript draft. CB-T conceived the study and designed the figure. FC and DM-d-S conceived the study, supervised the process, and finalized the manuscript. All authors approved the final version of the manuscript.

FUNDING

DG-J, AF, GS, CB-T, FC, and DM-d-S are supported by the São Paulo Research Foundation (FAPESP, grant numbers 2018/ 25439-9; 2017/25588-1; 2018/03673-0; 2018/10362-0, 2017/ 25055-3; 2019/22398-2). AA and FC are supported by the Coordination for the Improvement of Higher Level Personnel (CAPES/BRAZIL, grant number 465412/2014-9—INBioN).

ACKNOWLEDGMENTS

The authors wish to thank Bradley Smith, MSc for critical comments and English review support during the process.

ABSTRACT

Schizophrenia is a psychiatric disorder that affects 1% of people worldwide. Antipsychotics are the most commonly chosen option for treatment, and are effective in regards to positive symptoms; however, they are oftentimes not useful for treating negative or cognitive symptoms. All three classes of symptoms have been found to be associated with neuronal dysconnectivity, which has also been implicated in oligodendrocyte abnormalities in white matter. In this context, we developed an *in vitro* assay of cuprizone-mediated death in a human oligodendrocyte precursor cell line (MO3.13) to test the effects of antipsychotics (clozapine and haloperidol), cannabidiol and benztropine in terms of their potential protective effects. After the treatments mentioned above, the proteome was extracted and digested for analysis by nano-chromatography coupled with mass spectrometry to investigate the proteins and pathways affected in oligodendrocytes that were treated by these drugs. We confirm that the *in vitro* model for cuprizone cell death is cytotoxic to MO3.13 oligodendrocyte viability through disturbances of several biological processes, including energy and lipid metabolism, genetic processes and growth signaling. Furthermore, the administration of antipsychotics, cannabidiol, and benztropine seems to modulate metabolism, genetic factors, cell cycle, and cell signaling, pathways related to cuprizone-induced cell death, indicating their potential to act against the cuprizone toxic effect. In conclusion, although modeling OL death with cuprizone does not represent the entirety of the pathophysiology of the disorder, these results provide insight into the mechanisms related to antipsychotics' and cannabidiol's effects against the cuprizone toxicity effect and their implications for developing new pharmaceutical targets and treatment options for schizophrenia.

Keywords: antipsychotics, cannabidiol, cuprizone, MO3.13 oligodendrocyte, schizophrenia.

INTRODUCTION

Schizophrenia is a severe and chronic mental disorder characterized by positive (delusions and hallucinations), negative (lack of motivation, poverty of speech, and social withdrawal) and cognitive symptoms (slower information processing and impaired working memory) (Azorin et al. 2014; Owen et al. 2016). Treatment is based on antipsychotics, which are classified as typical, such as haloperidol, or atypical, including clozapine, the prototype of this drug class (Leucht et al. 2009; van Os and Kapur 2009) and has since become an important treatment option in the clinic. Typical antipsychotics are D₂ receptor antagonists and are effective in reducing the positive symptoms, but often cause extrapyramidal side effects (Howes et al. 2015; Howes and Kapur 2009). In contrast, atypical compounds have an affinity for both D₂ and 5-HT₂ receptors, and can additionally attenuate negative symptoms more than typical antipsychotics (Leucht et al. 2009).

In regards to the physiopathology of schizophrenia, symptoms have been associated with white matter abnormalities and brain dysconnectivity (Bernard et al. 2015; Orban et al. 2017; Saito et al. 2018). Several findings suggest that neuronal dysconnectivity occurs via a dysfunction in axon myelination due to oligodendrocyte (OL) disturbances (Cassoli et al. 2015; Jørgensen et al. 2016; Vikhrev et al. 2016). These glial cells are responsible for forming the myelin sheath in the central nervous system (CNS), ensuring efficient impulse conduction and providing metabolic support for neurons (Buntinx et al. 2003; Lee et al. 2011; Simons and Nave 2015). Studies have demonstrated an abnormality in the expression of genes and proteins related to myelin and OLs in post-mortem brain samples of schizophrenia patients (Georgieva et al. 2006; Saia-Cereda et al. 2015; Voineskos et al. 2008). Additionally, alterations in the density, distribution, and morphology of these cells have been seen in schizophrenia patients (Bernstein et al. 2015; Uranova et al. 2018; Vikhrev et al. 2016). Studies have also shown impairments in oligodendrogenesis and differentiation of the oligodendrocyte progenitor cells (OPCs) in schizophrenia (Hattori et al. 2014; Santos et al. 2019). Thus, the biology of the OPCs and mature OLs is an important hub to understand the role of these cells in the pathophysiology of -- and the development of new treatment for -- schizophrenia (de Almeida and Martins-de-Souza 2018).

Several findings suggest that antipsychotics and cannabidiol affect myelin and OLs, indicating their potential therapeutic in neurodegenerative disorders and schizophrenia (Bartzokis et al. 2007; Bartzokis et al. 2009; Rahimi et al., 2015; Zajicek & Apostu, 2011).

Benztropine is a molecule used for treatment of Parkinson's disease, and enhances OLs differentiation and myelination in an *in vitro* and *in vivo* model (Deshmukh et al., 2013; Ettle et al., 2016; Thompson et al., 2018). That drug probably acts in immature OL and the muscarinic receptors antagonism is the mechanism of action (Deshmukh et al., 2013; Ettle et al., 2016). However, the role of these receptors and the molecular mechanism involved in improvement of myelination and OL differentiation is unclear.

In this context, the molecular mechanisms involved in demyelination, remyelination, and oligodendrocyte abnormalities are investigated by the cuprizone demyelination model. Cuprizone is a copper-chelating agent that inhibits several enzymes that use copper as a cofactor, including cytochrome oxidase, succinyl dehydrogenase and monoamine oxidase (Messori et al. 2007; Petronilli and Zoratti 1990; Venturini 1973). Consequently, this drug induces OL apoptosis, microglial activation and demyelination in the corpus callosum, hippocampus, and superior cerebellar peduncle in the animal models of demyelination (Goldberg et al. 2013; Sachs et al. 2014). Disturbances of energy and protein metabolism have been reported as the molecular mechanisms of cuprizone toxicity, in addition to the resulting increases in oxidative and endoplasmic reticulum stress in OLs (Biancotti et al. 2008; Goldberg et al. 2013; Praet et al. 2014; Taraboletti et al. 2017).

This study aimed to ascertain whether antipsychotics and cannabidiol induce protective molecular mechanisms, such as benztropine, against cuprizone-mediated toxicity in a human oligodendrocyte precursor cell line (MO3.13). Proteomic assays detected changes induced by antipsychotics (haloperidol and clozapine), cannabidiol, and benztropine in MO3.13 cells previously exposed to cuprizone.

METHODS

1. Cell culture and treatment

Human hybrid MO3.13 oligodendrocytes express phenotypic characteristics of immature OLs (Buntinx et al. 2003; Iwata et al. 2013). These cells have been used in our group to understand molecular mechanisms related to schizophrenia and its treatment (Brandão-Teles et al. 2019; Cassoli et al. 2016; Seabra et al. 2020). Here, MO3.13 cells were cultured in DMEM (Sigma) supplemented with 10% FBS and 1% penicillin/streptomycin and grown at 37°C and 5% CO₂ as described previously (Brandão-Teles et al. 2017; Iwata et al. 2013).

Stocks of cuprizone (28,05mM; Sigma), haloperidol (53mM; Cristália), clozapine (25mM; Cristália), or cannabidiol (25mM; USP Ribeirão) were made in DMSO, and the final concentration of DMSO in the medium was limited to 0.042%. Benztropine (6mM) was dissolved in ddH₂O. Saline in DMSO (final concentration of DMSO in medium 0.042%) was used as a control. Based on our pilot experiments and previous studies (Bénardais et al. 2013; Deshmukh et al. 2013; Etle et al. 2016; Mecha et al. 2012; Xu et al. 2014), MO3.13 cells were seeded in six-well plates at a density of 115.000 cells/well and treated with 10µM of cuprizone for 48 hours or with 1µM of haloperidol, clozapine, cannabidiol, or benztropine for 24 hours. For the co-treatment, the cells were treated with cuprizone for 48 hours, with the other drugs being added for the last 24 hours of the treatment, all at the previously mentioned concentrations.

2. MTT assay

For MTT assays, cells were seeded in 96-well plates at a density of 7.000 cells/well for 24 hours. After incubation, the medium was aspirated and replaced with new media containing increasing concentrations of cuprizone for 48 hours, or haloperidol, clozapine, cannabidiol, or benztropine for 8 hours. Following the treatment, 0.5mg/mL of MTT was added to each well. Each plate was incubated for 2 hours at 37°C; ethanol, 100% was added and the absorbance was read at 570 nm on a plate spectrophotometer. Data are expressed as mean ± SEM and one-way analysis of variance (ANOVA) was used to analyze the statistical significance, followed by Dunnett post hoc test. ($p < 0.05$).

3. Proteome extraction

After treatment, cells were collected and centrifuged at 4°C and 1,200xg for 5 min. The pellets were homogenized in a lysis buffer (Tris pH 6,8, 1 M; SDS 20%) with protease

inhibitor (final working concentration, 1x; Roche; Mannheim, Germany). Each sample underwent a short run through a polyacrylamide gel to remove buffer salts and other contaminants before peptide digestion was performed *in gel*. 100µL of 10mM of dithiothreitol stock (15.4mg DTT in 10mL of 50mM ammonium bicarbonate - Ambic), 100µL of 55mM of iodoacetamide stock (102mg IAA in 10mL of 50mM Ambic), and 200µL of acetonitrile 100% were added in each sample. Proteins were digested by trypsin for 16-18 hours at 37°C and the peptide concentrations were determined by the BSA assay kit (Sigma).

4. NanoLC-ESI MS/MS

Proteomic analyses were performed in a bidimensional nanoAcquity UPLC M-Class (Waters Corporation, Milford, MA) coupled to a Synapt G2-Si mass spectrometer (Waters Corporation, Milford, MA). The samples were fractionated in 5 fractions using discontinuous steps of acetonitrile (11.4, 14.7, 17.4, 20.7, and 50%) before separation with a continuous acetonitrile gradient from 7% to 40% (v/v) on reverse-phase C18 columns. MS/MS analyses were performed in data-independent acquisition (DIA) mode using UDMS^E after performing a manual ion selection method profile for each fraction using DriftScape (version 2.9).

5. Data processing and protein identification

MS/MS spectra were analyzed with Progenesis® QI for Proteomics (version 3.1) with Apex3D, peptide 3D, and ion accounting informatics (Waters). Proteins were identified using the Reviewed Uniprot human database (obtained 11/2019) and quantified using the Top3 method. The following parameters were used in the identification of peptides/proteins: Digestion by trypsin with a maximum of one missed cleavage; Maximum protein mass of 600 kDa; False discovery rate (FDR) less than 1%; at least two fragments per peptide; Two or more peptides per protein; Five or more fragments per protein; One or more unique peptide per protein; and a mass error ≤ 20 ppm. Proteins were considered to be differentially expressed when one-way analysis of variance (ANOVA) returned a p-value < 0.05 .

6. *In silico* analyses

Affected biological processes and biochemical pathways were analyzed using Reactome (Fabregat et al. 2018), David bioinformatics database (Huang et al. 2009; Huang et al. 2009), and Proteomaps (Liebermeister et al. 2014). Biological processes and protein networks were analyzed using Metascape (Zhou et al. 2019), Cytoscape (Franz et al. 2016; Szklarczyk et al. 2017) and ClustVis (Metsalu and Vilo 2015).

RESULTS

1. MTT assay

To determine cuprizone toxicity, we performed an *in vitro* assay of cuprizone-induced death on the oligodendrocyte cell line MO3.13. These cells were treated with increasing concentrations of cuprizone for 48 hours and viability was measured with the MTT assay. All cells treated with cuprizone displayed a loss of viability after 48 hours (figure S1).

We confirmed that the concentrations used in previous studies for these antipsychotics, cannabidiol, and benztropine (Deshmukh et al. 2013; Mecha et al. 2012; Xu et al. 2014) are not cytotoxic to the MO3.13 cell line under this experiment's conditions. To do so, we used the MTT assay to ensure that the cytotoxic cutoff for these compounds is sufficiently above these concentrations after 8 hours of incubation. As the concentrations tested were increased, viability dropped to a significant degree after 75µM of clozapine, 50µM of haloperidol, 4µM of cannabidiol and 100µM of benztropine (figure S2). This confirmed that the previously used concentrations of 10µM for cuprizone induces a cytotoxic effect in these cells and 1µM for antipsychotics, cannabidiol and benztropine (Bénardais et al. 2013; Deshmukh et al. 2013; Taraboletti et al. 2017; Xu et al. 2014) are not cytotoxic and were used during treatment and co-treatment assays for subsequent proteomic analysis.

2. Proteomic analyses

2.1 Proteome of oligodendrocytes treated with benztropine, antipsychotics or cannabidiol

We identified a total of 196 differentially expressed proteins in OLs treated with benztropine (table S1). This drug can affect pathways related to metabolic processes, metabolism of RNA, cell cycle, post-translational modification, immune system and cell redox homeostasis (figure 1 and table S10). When compared to cells treated with vehicle alone, treatment with haloperidol, clozapine or cannabidiol resulted in 91, 292, and 106 differentially expressed proteins, respectively (table S1). Cells treated with clozapine and benztropine had the most overlap of gene names among all groups (figure 2A). Regarding biological processes, all drugs caused changes in RNA metabolism, regulation of chromosome organization, regulation of mRNA metabolic processes, protein localization to the nucleus, the microtubule-based process, regulated exocytosis, RHO GTPase effectors and membrane trafficking (figure 2B).

Figure 1. Bar graph of enriched biochemical pathways in MO3.13 cells treated with benztropine, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are represent between 10^{-20} to 10^{-2} .

2.3 Proteome of oligodendrocytes treated with cuprizone

A total of 2019 and 1774 proteins were identified and quantified, respectively, 30 of which were differentially expressed in OLs in response to cuprizone treatment (figure 3 and table S1). Citrate synthase (CS) and AMP deaminase 2 (AMPD2), both metabolism-related proteins, were among those differentially expressed. Thioredoxin-dependent peroxide reductase (PRDX3) and E3 ubiquitin/ISG15 ligase (TRIM25), of the immune system, were also present. Serine/arginine-rich splicing factor 9 (SRSF9), related to genetic information processing, and annexin 5 (ANX5) and 26S proteasome non-ATPase regulatory subunit 4 (PSMD4), both associated with apoptosis, were also found (figure 4). Overall, it appears that cuprizone can affect, to a certain degree, pathways related to translation, transcription, signal transduction and DNA maintenance (ribonucleoprotein complex assembly), as well as affecting biosynthesis pathways (carboxylic acid biosynthetic process), the immune system, biological process response to stress, AKT signaling and the cellular process plasma membrane-bounded cell projection assembly (figure 5 and table 1).

Figure 3. Proteins differentially expressed in OLs treated with 10 μ M of cuprizone (CUP) for 48 hours, compared to the vehicle (VEH), created with ClustVis.

Figure 4. Prospective network interaction of proteins differentially expressed on oligodendrocytes treated with cuprizone. The network was generated in Cytoscape from differentially expressed proteins resulting from cuprizone treatment (10μM, 48h). Colored lines represent a strong interaction; red spheres are upregulated proteins; blue spheres are downregulated proteins. All colored spheres represent $p < 0.05$; to better show potential interconnectivity, gray spheres were added with a higher cutoff ($p < 0.10$).

Figure 5. Bar graph of the enriched pathways in OLs resulting from cuprizone treatment (10μM, 48h), generated with Metascape.

Table 1. Biochemical pathways highlighted in treatment with cuprizone (10μM, 48h), generated with Reactome.

Biochemical pathway	p-value
FGFR4 mutant receptor activation	0.003
betaKlotho-mediated ligand binding	0.008
Formation of the active cofactor, UDP-glucuronate	0.008
Collagen biosynthesis and modifying enzymes	0.013
Nef Mediated CD8 Down-regulation	0.021
Collagen formation	0.023
PCP/CE pathway	0.024
EPH-Ephrin signaling	0.024
Nef Mediated CD4 Down-regulation	0.026
Signaling by FGFR4 in disease	0.031
NF-kB activation through FADD/RIP-1 pathway mediated by caspase-8 and -10	0.031
VLDLR internalization and degradation	0.031
WNT5A-dependent internalization of FZD2, FZD5, and ROR2	0.034
Purine salvage	0.034
PIP3 activates AKT signaling	0.035
FGFR4 ligand binding and activation	0.036
Retrograde neurotrophin signaling	0.036
TRAF3-dependent IRF activation pathway	0.036
p38MAPK events	0.036
Signaling by NTRK1 (TRKA)	0.038
Phospholipase C-mediated cascade; FGFR4	0.039

Trafficking of GluR2-containing AMPA receptors	0.044
Platelet degranulation	0.045

2.4 Proteome of oligodendrocytes co-treated with cuprizone and antipsychotics, cannabidiol, or benztropine

When compared to cells treated with cuprizone alone, co-treatment with cuprizone and either haloperidol (CupHal), clozapine (CupClz), cannabidiol (CupCBD), or benztropine

(CupBenz) resulted in 95, 91, 74, and 113 differentially expressed proteins, respectively (table S1). In the antipsychotics groups, proteins were mostly associated with metabolism; the immune system; the cytoskeleton; signal transduction; the genetic information process; cell growth; and cell death. In response to cannabidiol co-treatment, proteins related to energy and lipid metabolism, signal transduction and the genetic information process. Finally, the benztropine co-treatment modulated proteins related to amino acid and lipid metabolism; cellular response to external stimuli (such as amino acid deficiency and DNA damage); signaling transduction; the cytoskeleton; and the genetic information process.

The changes seen in the CupBenz group had some similarities in affected genes when compared with the changes induced by other treatment groups: CupHal, 12 genes (3.8% of total significantly altered genes); CupCLZ, 4 (1.3%); and CupCBD, 10 (3.2%) (figure 6A). All co-treatments caused changes ($-\log_{10}(P):10^{-20}$ to 10^{-2}) in proteins related to RNA metabolism, ribonucleoprotein complex biogenesis, nuclear-transcript mRNA catabolic process, the cell cycle and supramolecular fiber organization (figure 6B). Some biological processes were not found in all co-treatments, such as the ATP metabolic process, altered only in the co-treatment with cannabidiol, and the cellular amino acid metabolic process was changed by benztropine and haloperidol co-treatments (figures 6, S7A, and S7B).

Figure 6. Chord diagram where purple curves link identical genes between cuprizone treatment (Cup) and co-treatment with cuprizone and clozapine (CupClz), cannabidiol (CupCBD), haloperidol (CupHal) or benztropine (CupBenz) (A); and a heatmap of enriched pathways of oligodendrocytes co-treated with cuprizone and haloperidol, cannabidiol, clozapine, or benztropine (B), created in Metascape.

DISCUSSION

Comparing the effects of antipsychotics and cannabidiol with the putative protective effects of benztropine on the proteome of MO3.13 oligodendrocytes

Several studies have demonstrated that many antipsychotics, cannabidiol, and benztropine all have the potential to influence oligodendrocytes (OLs) and induce myelination (Deshmukh et al. 2013; Ren et al. 2013; Xu et al. 2014; Zajicek and Apostu 2011). Here, we found changes in the constituent proteins of several molecular mechanisms and biological processes in OLs resulting from the administration of benztropine, which induces oligodendrocyte progenitor cell (OPC) differentiation and myelination (Deshmukh et al. 2013). We then compared these results with MO3.13 OLs treated with two antipsychotics (haloperidol and clozapine) and cannabidiol, in terms of their hypothesized ability to induce protective molecular mechanisms.

Lipid and Energy Metabolism

Benztropine is a molecule that is known to be able to improve myelination; but a comprehensive understanding of its mechanism of action beyond its primary interacting partners is still lacking (Deshmukh et al. 2013; Ettle et al. 2016). This drug enhances membrane and cholesterol biogenesis in OLs and induces OL formation by decreasing the basal level of sterol (Ettle et al., 2016; Hubler et al. 2018). Benztropine treatment modulates proteins related to the glycolytic, lipid and amino acid pathway (figure 1 and table S10). Our findings reported that benztropine treatment downregulated the levels of 3-hydroxyacyl-CoA dehydrogenase, type-2, which act in mitochondrial fatty acid beta-oxidation (He et al. 1998). Levels of delta (24)-sterol reductase were also found upregulated by benztropine, which reduces an intermediate in cholesterol metabolism and protects cells against oxidative stress (table S15). These results support the hypothesis that benztropine induces myelination and protective effect on OL by molecular mechanisms.

Studies have reported that some drugs such as antipsychotics and cannabidiol can have protective effects against energy deprivation by modulating glucose metabolism (Steiner et al. 2011; Steiner et al. 2014; Sun et al. 2017). In studies involving MK-801, an NMDA receptor antagonist and model for schizophrenia (Li et al. 2013; Paulson et al. 2004), clozapine treatment after MK-801 exposure was found to decrease ALDOC levels, a glycolytic enzyme, and increases cholesterol and triacylglycerol levels in schizophrenia patients (Cassoli et al. 2016; Wu et al. 2006). Haloperidol administration alone similarly modulates proteins related to glycolysis and gluconeogenesis but inhibits cholesterol biosynthesis in cultured cells (Brandão-Teles et al. 2019; Sánchez-Wandelmer et al. 2010). Confirming that haloperidol and clozapine alters cholesterol metabolism in MO3.13 cells has pharmacological relevance to the long-term administration of these drugs. Studies have demonstrated that cannabidiol can attenuate cell damage by promoting mitochondrial function and biogenesis, modulating glucose metabolism via the pentose-phosphate pathway in neurons (Hao et al. 2015; Scarpulla 2011; Sun et al. 2017) and finding that cannabidiol also alters metabolic pathways in MO3.13 cells (figure S5), both supports the previous studies and also helps to validate these findings. As such, the protective effects of these drugs in OLs can be attributed to a modulation of metabolism, similar to benztropine. Moreover, finding that benztropine modulates proteins related to the glycolytic pathway (table S10), just as cannabidiol and antipsychotics do, suggests that this may be a mechanism of action in common, also behind the protective effects of benztropine.

Antioxidant Defense and Stress Pathways

Another set of proteins modulated by benztropine were related to antioxidant defense, selenocysteine synthesis and response to endoplasmic reticulum stress (figure 1 and table S10). When antioxidant defense is insufficient, oxidative stress may occur and it plays a known role in the pathophysiology of schizophrenia (Martins-de-Souza et al. 2011; Sawa and Sedlak 2016). Benztropine exerts effects on neuronal cells, increasing glutathione levels and can reduce the elevated ROS levels induced by oxaliplatin and cell death (Cerles et al., 2019). In contrast, benztropine had an effect on the levels of certain proteins related to antioxidant defense. Antioxidant molecules decrease the ROS level in OPCs; however, some promote OPC to OL differentiation, independent of their antioxidant effect and can therefore promote remyelination (Guo et al., 2018). Here, we suggest that this may be a mechanism of action behind the protective effects of benztropine in OLs. Like benztropine, haloperidol and cannabidiol also modulated proteins related to selenocysteine synthesis (table S7 and S9). While haloperidol has been suggested to induce oxidative stress in rat brains (Andreazza et al. 2015) cannabidiol has been observed to prevent hydrogen peroxide (H₂O₂)-induced apoptosis in nucleus pulposus cells as well as decrease oxidative species in OPCs (Chen et al. 2016; Mecha et al., 2012), suggesting a possible cause of the differences in the side effect profiles of cannabidiol versus haloperidol.

Similar to our data, studies have reported alterations in proteins responsible for immune system processes and the cell cycle in benztropine treatment (Deshmund et al., 2013; Kudriaeva et al., 2016). Here, we identified ubiquitin and proteasome proteins related to the immune system (figure 1 and table S15). At a molecular level, ubiquitin-proteasome machinery, which is found altered in neurodegenerative disorders, links the immune and neuronal system modulating neurotransmission, oxidative and inflammatory stress, cell cycle and differentiation (Limanaqi et al., 2019; Zheng et al., 2014). The cell progression is inhibited in benztropine-treated OPCs indicating that the drug induces differentiation in immature OL (Deshmund et al., 2013). As such, our results suggest that the efficacy of benztropine is due to an increase in myelination by enhancing oligodendrogenesis and modulating the immune system at molecular level. Moreover, clozapine and cannabidiol also modulated the cell cycle and immune system (table S8-S9 and figure S4-S5). Studies have shown that another atypical antipsychotic, quetiapine which acts in dopamine and serotonin receptors, promotes the cell cycle, OL differentiation, and modulates genes involved in the cell cycle (Mi et al. 2018; Sárvári et al. 2014), and haloperidol has been found to promote

proliferation of rat OPCs (Niu et al. 2010). Here, haloperidol treatment modulated signal transduction by p53 class mediator (figure S3), whose overexpression mediates OL apoptosis (Ma et al., 2017). Along those lines, cell cycle and proliferation changes caused by antipsychotics can be correlated with their long-term administration, differently impacting OLs and expression of myelin in schizophrenia patients (Bartzokis et al., 2007; Bartzokis et al., 2009). Although cannabidiol induces cell cycle arrest in human gastric cancer cells at the G0–G1 phase, reducing cell proliferation (Zhang et al., 2019), it promotes cell proliferation in neural stem cells and neurogenesis (Hill et al., 2018), supporting the hypothesis that cannabidiol promotes OL proliferation by modifying the cell cycle.

Amino Acid Metabolism and Splicing

Proteins related to amino acid metabolism and splicing were also modulated by benztropine, clozapine and cannabidiol treatment (figure S5-6, table S8). Spliceosome machinery has already been documented to be affected by clozapine and haloperidol, especially regarding hnRNPs (Brandão-Teles et al. 2019; Cassoli et al. 2016) and abnormalities in RNA splicing and phosphorylation have already been linked to demyelination and psychiatric disease (Glatt et al. 2011; Szilagyi et al. 2020). More specifically, alterations in alternative splicing and decreases in mRNA-associated genes have been documented in schizophrenia (Cohen et al. 2012; Prabakaran et al. 2004; Saia-Cereda et al. 2017; Santarelli et al. 2019). Therefore, RNA splicing can be another potential therapeutic target of benztropine in the demyelination model.

Lastly, benztropine treatment also modulated proteins related to post-translational modification, being methylation (string, FDR: 1.31e-07) and acetylation (string, FDR: 4.16e-4). Acetylation pathways were also affected by cannabidiol (string, FDR: 4.70e-20) and the two antipsychotics (string, FDR: 1.02e-20; 7.00e-59). Alterations in acetylation and methylation of DNA and proteins have been related to neurodegenerative disorders (Mattson 2003). Furthermore, histone acetylation, which is coordinated by response to metabolic state such as influence of acetyl-CoA, is important for OL differentiation and myelination (Gao et al., 2016; Marin-Husstege et al., 2002) and some drug-mediated acetylation can protect against neurodegenerative events (Ayyadevara et al., 2017). We hypothesize that benztropine can also promote differentiation and myelination by modulating post-translational modification, and that it may be a common protective effect among benztropine, antipsychotics and cannabidiol.

Cuprizone's effects on the proteome of MO3.13 oligodendrocytes

Several models have been created or are under development to comprehend myelination, demyelination, and remyelination mechanisms, including the *in vitro* and *in vivo* cuprizone demyelination model (Bénardais et al. 2013; de Rosa et al. 2019; Taraboletti et al. 2017; Sachs et al. 2014; Xu et al. 2014; Xu et al. 2019; Zahednasab et al. 2019). In this study, we searched for the molecular mechanisms and biological processes that are involved in, and potentially directly behind, cuprizone-mediated toxicity in OLs.

One pathway with altered protein levels in response to OL exposure to cuprizone was NF- κ B signaling (table 1). This pathway is known to modulate cell proliferation and myelination by OLs, and can be activated by inflammatory factors, neurotrophic factors, neurotransmitters, and cellular stress molecules (Arnett et al. 2001; Hayden and Ghosh 2008). In some studies on cuprizone models, NF- κ B signaling was found to be critical for toxic demyelination and OL death, with its modulation leading to changes in apoptosis, remyelination, and OL differentiation (Elbaz et al. 2018; Raasch et al. 2011). The data obtained in this study further reinforce the role of the NF- κ B cascade in cuprizone-induced toxicity.

Cuprizone treatment also had an effect on some growth factor pathways, namely the activation of the FGFR4 receptor and neurotrophic receptor tyrosine kinase 1 (NTRK1, also known as tropomyosin receptor kinase A - TRKA) along with betaKlotho (KLB) signaling (table 1). Certain other soluble factors like fibroblast growth factor (FGF) and nerve growth factor (NGF) are already known to influence CNS myelination by inducing OL proliferation, differentiation, and migration (Bansal and Pfeiffer 1997; Park and Poo 2013). p38 mitogen-activated protein kinase (MAPK) -- a pathway that has a crosstalk with FGF signaling through FGFR and activates MAPK/ERK signaling, regulating myelination and OL maturation (Ahrendsen and Macklin 2013) -- was also found to be altered (table 1). Furthermore, the pathway "PIP3 (phosphatidylinositol (3,4,5) triphosphates) activates AKT (protein kinase B) signaling" was modulated by cuprizone (figure 5), which regulates cell proliferation and apoptosis (Liu et al. 2017). Taken together, these results suggest that cuprizone may lead to OL toxicity by affecting various growth factors and signaling mechanisms that are related to cell proliferation, survival, and myelination.

Proteins related to energy and lipid metabolism were also modulated by cuprizone treatment. Results showed that cuprizone affects, at least indirectly, some mitochondrial proteins,

specifically citrate synthase (figure 5 and table 1). Lipid metabolism may also be affected through changes in FGFR4 activation and VLDLR internalization and degradation (figure 5 and table 1), which are integral to lipogenesis, glucose and lipid homeostasis, and the inflammatory response, potentially also affecting the carboxylic acid biosynthetic process (Adighibe et al. 2006; Sodhi and Singh 2013; Viennois et al. 2011). These results are supported by the dysfunctions in energy and lipid metabolism that have been seen in the corpus callosum and hippocampus of animals administered cuprizone (Maganti et al. 2019; Taraboletti et al. 2017). Disturbances in lipid homeostasis affect OL biology and myelination overall, and an OL primary culture study indicated that these cells take up and use fatty acids for biosynthesis, functioning in brain lipid metabolism machinery (Hofmann et al. 2017).

Cuprizone is also known to disturb energy metabolism and can decrease glucose utilization (Kim et al. 2019; Taraboletti et al. 2017), additionally affecting NAD⁺ metabolism, blocking glycolytic pathways and energy production as a result (Fünfschilling et al. 2012; Taraboletti et al. 2017). Moreover, cuprizone administration impairs mitochondria and electron transport chain functionality, leading to a decrease in ATP production (Faizi et al. 2016). Such changes in lipid homeostasis and energy metabolism are especially relevant since OLs are especially vulnerable to metabolic and lipid disturbances, leading in turn to deregulations in proteins related to neuronal structure and transport, cell trafficking, and signal transduction, therefore contributing to a dysfunction in white matter and in neuronal connectivity (Chan et al. 2011; Guest et al. 2015; Hofmann et al. 2017).

Lastly, some proteins related to genetic processes including translation, post-translational modifications, and spliceosome processes (figure 5 and table 1) were found to be dysregulated upon exposure to cuprizone. One post-translational protein modification has already been linked with cuprizone in an *in vivo* study involving mice that found altered levels of phosphorylation on MBP (myelin basic protein) (Szilagyi et al. 2020). Splicing is an important form of RNA processing performed by the spliceosome that affects the translation of all human genes; aberrant splicing events have been confirmed in some neurological disorders, including schizophrenia and multiple sclerosis (Glatt et al. 2011; Hecker et al. 2019). A dysregulation of proteins that comprise the main component of splicing operations has also been reported in both the white and gray matter of patients with schizophrenia, and included the splicing factor serine/arginine-rich 3 (SRSF3) (Saia-Cereda et al. 2017). SRSF9 is involved in alternative pre-RNA splicing and its overexpression affects cell proliferation, cycle arrest, and apoptosis (Bressan et al. 2009; Zhang et al. 2019), and

was found dysregulated in the OLs exposed to cuprizone (figure 4). Thus, these results suggest that the deregulation of proteins related to spliceosome function and post-translational processes can result in cell death in OLs exposed to cuprizone.

The cuprizone model has already been established and used to understand the mechanisms behind OL and myelination dysfunctions. These previous data have been supplemented with the findings of this study, which have determined or confirmed that alterations in proteins involved in metabolic processes, the immune system, genetic factors, signaling pathways, and the regulation of apoptosis can all occur in response to cuprizone. Four therapeutic drugs were then evaluated and compared in this model to understand their effects on MO3.13 OLs at the cellular and molecular levels, as well as their implications for myelination.

Effects of haloperidol, clozapine, cannabidiol, and benztropine on cuprizone-treated cells and their implications on cell survival and myelination

The third part of this study was to administer haloperidol, clozapine, cannabidiol, and benztropine in conjunction with cuprizone to visualize how the protective effects of these compounds may have an effect at the proteomic level. After exposure to cuprizone, one drug was administered, and overall, the resulting proteins that were modulated in response were related to metabolism, the processing of genetic information and the cell cycle.

As detailed in our results, cuprizone appeared to affect mitochondrial proteins and may therefore impair ATP production. Cannabidiol co-treatment also induced changes in ATP metabolic processes (figure 6B), in which modulated proteins were more specifically related to energy metabolism and mitochondrial biogenesis and included cytochrome b-c1 and ATP synthase. Thus, these data indicate a potential of cannabidiol to attenuate the energy metabolism disturbances seen in the cuprizone model. An overall reduction of protein and lipid levels is also observed in animals treated with cuprizone, impacting myelin formation and function (Maganti et al. 2019; Taraboletti et al. 2017). In our results, haloperidol, cannabidiol, and benztropine -- but not clozapine -- co-treatments all modulated proteins involved in lipid and steroid metabolism (tables S12-5). Interestingly, in an *in vivo* cuprizone model, clozapine treatment was unable to prevent demyelination during cuprizone administration, but did enhance functional support after demyelination (Templeton et al. 2019). Benztropine, however, has been found to induce OL formation by decreasing the basal level of sterol (Hubler et al. 2018), and cannabidiol can modulate cholesterol homeostasis and sterol metabolism in microglial cells (Rimmerman et al. 2011). Here, we demonstrated

that haloperidol, cannabidiol, and benztropine modulate proteins and pathways related to lipid metabolism throughout cuprizone insult, suggesting a potential ability to prevent demyelination events.

In cuprizone-treated mice and in schizophrenia, a deregulation of the expression of cell cycle genes has been found to contribute to deficits in OLs, cells which normally respond to injury by accelerating their cell cycle, indicating that CNS remyelination can be mediated by modulating the OPC cell cycle (Fan et al. 2012; Katsel et al. 2008; Palazuelos, et al. 2014). We identified a modulation of the cell cycle in all co-treatments (figure 6B), but this pathway was most significantly affected in co-treatments with haloperidol and clozapine. The antipsychotics modulated the mitotic anaphase, metaphase, prometaphase, and M phase (tables S3 and S4), whereas benztropine co-treatment modulated centrosome maturation, recruitment of mitotic centrosome proteins and complexes, G2/M transition, and mitotic G2-G2/M phases (table S6). Cannabidiol and benztropine co-treatments increased the protein SWI/SNF complex subunit SMARCC1, which is related to the cell cycle (table S2). Clozapine co-treatment decreased 26S proteasome non-ATPase regulatory subunit 6 that participates in many cellular processes, such as cell cycle progression, apoptosis and DNA damage repair (table S2). Though there is overlap between the two antipsychotics tested, each compound seems to affect the OL cell cycle in different ways; nonetheless, these compounds must be tested further regarding their potential to promote cell proliferation.

Lastly, cuprizone treatment was found to induce deregulations in proteins involved with DNA maintenance, spliceosome processes, translation, and post-translational modifications. Alterations in the expression and regulation of post-translational modifications can lead to dysfunctions in multiple cell types, brain regions, and neurotransmitters (Mueller and Meador-Woodruff 2020). All co-treatments modulated proteins related to the spliceosome and RNA metabolism (figure 6B), and was most significant in the co-treatment with haloperidol (figure S6). Moreover, the pathway Positive regulation of RNA splicing was found modulated by clozapine and haloperidol co-treatments (figure 6B), and post-translational modification was modulated by benztropine co-treatment (figure 6B). Though they affect these pathways in different ways, a more developed understanding of how these pathways are affected by antipsychotics, cannabidiol, and benztropine would be important to help determine how OPCs regenerate after toxic effects like those induced by cuprizone, and how schizophrenia and other demyelinating disorders can be better treated.

CONCLUSIONS

In this study, we identified biochemical pathways related to cuprizone toxicity. We confirmed that this *in vitro* model for cuprizone-induced cell death is cytotoxic to MO3.13 oligodendrocytes by disturbing biological processes that are related to the OL deficit hypothesis of schizophrenia. A thorough understanding of the mechanisms regulating myelination would help to develop pharmaceutical targets for the remyelination process, promoting recovery, and preventing the progression of schizophrenia symptoms. In this context, we evaluated the effects of two antipsychotics, cannabidiol, and benztropine on OPCs undergoing treatment with cuprizone; using a proteomic approach, we showed that all of the drugs modulate some biochemical pathways related to cuprizone's toxic effects. Cannabidiol mostly affected ATP production and lipid metabolism, indicating its similarity with benztropine and its potential effect to promote mitochondrial repair. In summary, haloperidol, clozapine, cannabidiol, and benztropine all modulated proteins related to the cell cycle, cell signaling, the spliceosome, and post-translational modifications, which are all pathways related to cuprizone-induced cell death, thus indicating their potential to combat the toxic effects of cuprizone. Even though this model of cuprizone-treated OLs does not represent the entirety of the pathophysiology of schizophrenia, these results allow us to better comprehend some facets of schizophrenia and other demyelinating disorders and to develop novel therapeutic targets and treatment options for OL disturbances.

7. CONCLUSÃO E PERSPECTIVAS

Como mencionado no decorrer desta dissertação, a esquizofrenia é uma desordem mental complexa e de caráter multifatorial. Sendo assim, o estudo desta desordem deve englobar estudos clínicos, biológicos e moleculares para sua compreensão. Estudos com tecido *post-mortem*, genéticos, proteômicos e de imagem relatam que os distúrbios na desconectividade neural e na substância branca, assim como anormalidades nos OLs e na mielina, podem estar relacionadas à fisiopatologia da esquizofrenia. Desta forma, modelos tóxicos de desmielinização, como o induzido por cuprizona, são utilizados para compreender os mecanismos moleculares relacionados aos distúrbios de OLs e de mielina. Neste processo, é de suma importância utilizar culturas de OPCs, para avaliar os efeitos de novos compostos químicos com potencial terapêutico.

Neste estudo, confirmamos que a cuprizona é capaz de induzir citotoxicidade em OLs da linhagem MO3.13, através de alterações em processos biológicos, os quais estão relacionados com a hipótese de déficits de OLs na esquizofrenia. Ademais, demonstramos que os antipsicóticos, CBD e a benztropina podem modular vias bioquímicas e proteínas relacionadas com os efeitos tóxicos induzidos pela cuprizona, como a alteração de proteínas relacionadas com o metabolismo, ao ciclo celular e à processos genéticos, evidenciando seus potenciais efeitos protetores. Desta forma, pretendemos contribuir para o melhor entendimento dos mecanismos relacionados às anormalidades de OLs e como se relacionam à fisiopatologia da esquizofrenia, além da sua relação com o desenvolvimento de futuros alvos terapêuticos para esta desordem. Sendo assim, trabalhos futuros que utilizem diferentes estágios celulares, como células neurais indiferenciadas e OLs em um estágio mais avançado de maturação, são de suma importância para avaliar os processos de diferenciação, efeitos inflamatórios, testar novos compostos químicos com potencial terapêutico, bem como desenvolver estratégias que ajudem atenuar estas anormalidades relacionados aos OLs e a mielina neste distúrbio.

9. MATERIAL SUPPLEMENTAR

Figure S1. An MTT assay was used to measure the percentage of live M03.13 cells at 48h with growth medium (DMEM), Vehicle (DMSO, 0.3%), and increasing cuprizone concentrations. (****, $P < 0.0001$; $n = 6$ wells/condition).

A

B

C

D

Figure S2. A MTT assay was used to measure the percentage of live M03.13 cells after 8h in growth medium (DMEM), Vehicle (haloperidol and cannabidiol, DMSO, 0.3%; clozapine, DMSO, 0.4%; benztropine was diluted in water), and increasing concentrations of haloperidol (A), clozapine (B), cannabidiol (C), or benztropine (D) (*, $P \leq 0.05$; ***, $P < 0.001$; ****, $P < 0.0001$; $n = 6$ wells/condition).

Figure S3. Bar graph of enriched biochemical pathways in M03.13 cells treated with haloperidol, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are representing between 10^{-20} to 10^{-2} .

Figure S4. Bar graph of enriched biochemical pathways in MO3.13 cells treated with clozapine, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are representing between 10^{-20} to 10^{-2} .

Figure S5. Bar graph of enriched biochemical pathways in MO3.13 cells treated with cannabidiol, colored by p-value, created in Metascape. Colored lines represent $-\log_{10}(P)$, which significance are representing between 10^{-20} to 10^{-2} .

A

B

Figure S6. The network of enriched terms colored by cluster ID (A) and by network-enriched terms, represented as a pie chart (B) in treatment with cuprizone and co-treatments with cuprizone and haloperidol, clozapine, cannabidiol or benztropine, created with Metascape.

Table S1. List of proteins identified, quantified, differentially regulated, upregulated, and downregulated in treatments and co-treatments with cuprizone (Cup) and haloperidol (Hal), clozapine (Clz), cannabidiol (CBD), or benztropine (Benz).

Condition	Identified	Quantified	Differentially regulated
Cuprizone	2.019	1.744	30 (↑11 ↓19)
Haloperidol	2.802	1.886	91(↑41 ↓50)
Clozapine	2.801	1.882	292 (↑163 ↓129)
Cannabidiol	2.804	1.884	106 (↑53 ↓53)
Benztropine	2.804	1.884	196 (↑77 ↓119)
CupHal	1.946	1.608	95 (↑43 ↓52)
CupClz	2.801	1.885	91 (↑27 ↓64)
CupCBD	1.947	1.608	74 (↑40 ↓34)
Cup Benz	1.944	1.604	113 (↑55 ↓58)

Table S2. List of the differentially expressed proteins (by ANOVA, $p \leq 0.05$) seen in response to cuprizone treatment, compared with the changes seen in response to cuprizone and either haloperidol (Hal), clozapine (Clz), cannabidiol (CBD), or benztropine (Benz). Hyphens represent that the protein was not identified or not quantifiable in that sample. Highlighted p-values represent a change (ANOVA, $p \leq 0.05$) in the opposite direction of that induced by cuprizone, indicating a reversal of its putative toxic effects.

Mitotic Metaphase and Anaphase	0.003
M Phase	0.005
Regulation of mRNA stability by proteins that bind AU-rich elements	0.006
Muscle contraction	0.007
Depolymerisation of the Nuclear Lamina	0.008
Metabolism of RNA	0.009
Initiation of Nuclear Envelope (NE) Reformation	0.012
Abortive elongation of HIV-1 transcript in the absence of Tat	0.015
Signaling by FGFR2 IIIa TM	0.015
Mitotic Prophase	0.017
FGFR2 alternative splicing	0.019
Signaling by FGFR in disease	0.022
mRNA Capping	0.024
Nuclear Envelope (NE) Reassembly	0.026
The role of GTSE1 in G2/M progression after G2 checkpoint	0.027
Formation of the HIV-1 Early Elongation Complex	0.03
Formation of the Early Elongation Complex	0.03
Cell Cycle, Mitotic	0.031
Drug resistance in ERBB2 KD mutants	0.032
Hypusine synthesis from eIF5Alysine	0.032
Drug-mediated inhibition of ERBB2 signaling	0.032
Resistance of ERBB2 KD mutants to afatinib	0.032

Table S5. Biochemical pathways highlighted in co-treatment with 10 μ M of cuprizone for 24 hours and 1 μ M of cannabidiol for an additional 24 hours (CupCBD), compared to cuprizone treatment alone, generated by Reactome.

Biochemical pathways - CupCBD	p-value
Nephrin family interactions	4.76e-04
Platelet degranulation	0.002
Response to elevated platelet cytosolic Ca ²⁺	0.002
Unwinding of DNA	0.003
Glutamate and glutamine metabolism	0.004
Collagen biosynthesis and modifying enzymes	0.01
rRNA processing	0.01
Orc1 removal from chromatin	0.011
Golgi-to-ER retrograde transport	0.012
Defective SLC7A7 causes lysinuric protein intolerance (LPI)	0.013
DNA strand elongation	0.019
Activation of the pre-replicative complex	0.02
Collagen formation	0.021
Switching of origins to a postreplicative state	0.022
Striated Muscle Contraction	0.023
Lysosome Vesicle Biogenesis	0.024
Activation of ATR in response to replication stress	0.024
Suppression of autophagy	0.026
The citric acid (TCA) cycle and respiratory electron transport	0.028
Formation of a pool of free 40S subunits	0.029
Platelet activation, signaling and aggregation	0.029
Major pathway of rRNA processing in the nucleolus and cytosol	0.031
NOSTRIN mediated eNOS trafficking	0.032
tRNA processing in the mitochondrion	0.032
L13a-mediated translational silencing of Ceruloplasmin expression	0.037

Table S6. Biochemical pathways highlighted in co-treatment with 10µM of cuprizone for 24 hours and 1µM of benztropine for an additional 24 hours (CupBenz), compared to cuprizone treatment alone, generated by Reactome.

Biochemical pathways - CupBenz	p-value
DNA Damage Recognition in GG-NER	7.12e-04
GTP hydrolysis and joining of the 60S ribosomal subunit	0.001
Influenza Life Cycle	0.001
Centrosome maturation	0.002
Recruitment of mitotic centrosome proteins and complexes	0.002
Cap-dependent Translation Initiation	0.002
Eukaryotic Translation Initiation	0.002
Influenza Infection	0.002
COPI-independent Golgi-to-ER retrograde traffic	0.002
Nonsense Mediated Decay (NMD) independent of the Exon Junction Complex (EJC)	0.003
Ribosomal scanning and start codon recognition	0.004
G2/M Transition	0.005
Mitotic G2-G2/M phases	0.005
Influenza Viral RNA Transcription and Replication	0.005
Intra-Golgi and retrograde Golgi-to- ER traffic	0.006
Loss of proteins required for interphase microtubule organization from the centrosome	0.006
Loss of Nlp from mitotic centrosomes	0.006
L13a-mediated translational silencing of Ceruloplasmin expression	0.007
AURKA Activation by TPX2	0.007
Nonsense-Mediated Decay (NMD)	0.008
Nonsense Mediated Decay (NMD) enhanced by the Exon Junction Complex (EJC)	0.008
Signaling by ROBO receptors	0.008

Table S7. Biochemical pathways highlighted in treatment with 1 μ M of haloperidol for 24 hours (Hal) compared to vehicle samples, generated by Reactome.

Biochemical pathways - Hal	p-value
Selenocysteine synthesis	1.27e-06

Eukaryotic Translation Elongation	1.37e-06
Translation	5.84e-06
Selenoamino acid metabolism	6.68e-06
Eukaryotic Translation Initiation	7.54e-06
Cap-dependent Translation Initiation	7.54e-06
Peptide chain elongation	1.08e-05
Influenza Infection	1.30e-05
Eukaryotic Translation Termination	1.42e-05
Nonsense Mediated Decay (NMD) independent of the Exon Junction Complex (EJC)	1.63e-05
Viral mRNA Translation	2.24e-05
Formation of a pool of free 40S subunits	2.39e-05
Response of EIF2AK4 (GCN2) to amino acid deficiency	2.39e-05
Metabolism of proteins	3.97e-05
L13a-mediated translational silencing of Ceruloplasmin expression	4.30e-05
SRP-dependent cotranslational protein targeting to membrane	4.55e-05
GTP hydrolysis and joining of the 60S ribosomal subunit	4.55e-05
Nonsense-Mediated Decay (NMD)	5.65e-05
Nonsense Mediated Decay (NMD) enhanced by the Exon Junction Complex (EJC)	5.65e-05
Cellular responses to stress	5.91E-05
Cellular responses to external stimuli	7.77e-05
Signaling by ROBO receptors	8.45e-05
Regulation of expression of SLITs and ROBOs	9.48e-05
Major pathway of rRNA processing in the nucleolus and cytosol	1.45e-04
rRNA processing in the nucleus and cytosol	2.07e-04

Table S8. Biochemical pathways highlighted in treatment with 1 μ M of clozapine for 24 hours (Clz) compared to vehicle samples, generated by Reactome.

Biochemical pathways - Clz	p-value
----------------------------	---------

Cytosolic tRNA aminoacylation	2.88e-07
Translation	9.91e-07
tRNA Aminoacylation	1.70e-05
Metabolism of RNA	3.52e-05
Glutamate and glutamine metabolism	5.13e-05
Influenza Infection	5.35e-05
Translation initiation complex formation	1.77e-04
Ribosomal scanning and start codon recognition	1.77e-04
Activation of the mRNA upon binding of the cap-binding complex and eIFs, and subsequent binding to 43S	1.98e-04
GTP hydrolysis and joining of the 60S ribosomal subunit	2.10e-04
Processing of Capped Intron-Containing Pre-mRNA	2.65e-04
Golgi-to-ER retrograde transport	2.84e-04
Citric acid cycle (TCA cycle)	3.01e-04
mRNA Splicing - Major Pathway	3.01e-04
Cap-dependent Translation Initiation	3.47e-04
Eukaryotic Translation Initiation	3.47e-04
Metabolism of amino acids and derivatives	3.71e-04
mRNA Splicing	4.62e-04
Formation of the ternary complex, and subsequently, the 43S complex	4.67e-04
Pyruvate metabolism and Citric Acid (TCA) cycle	6.48e-04
EPH-Ephrin signaling	7.53e-04
L13a-mediated translational silencing of Ceruloplasmin expression	7.80e-04
Metabolism of proteins	8.28e-04
RMTs methylate histone arginines	0.002
Gluconeogenesis	0.002

Table S9. Biochemical pathways highlighted in treatment with 1 μ M of cannabidiol for 24 hours (CBD) compared to vehicle samples, generated by Reactome.

Biochemical pathways - CBD	p-value
----------------------------	---------

L13a-mediated translational silencing of Ceruloplasmin expression	1.17e-06
GTP hydrolysis and joining of the 60S ribosomal subunit	1.26e-06
Eukaryotic Translation Initiation	2.05e-06
Cap-dependent Translation Initiation	2.05e-06
Metabolism of amino acids and derivatives	2.20e-06
Regulation of expression of SLITs and ROBOs	4.94e-04
Influenza Infection	4.94e-04
Formation of a pool of free 40S subunits	4.94e-04
Signaling by ROBO receptors	5.02e-04
Major pathway of rRNA processing in the nucleolus and cytosol	6.14e-04
SRP-dependent cotranslational protein targeting to membrane	7.50e-04
rRNA processing in the nucleus and cytosol	8.02e-04
Translation	0.001
rRNA processing	0.001
Peptide chain elongation	0.001
Nervous system development	2.76e-05
Eukaryotic Translation Termination	3.06e-05
Selenocysteine synthesis	3.06e-05
Eukaryotic Translation Elongation	3.27e-05
Nonsense Mediated Decay (NMD) independent of the Exon Junction Complex (EJC)	3.50e-05
Viral mRNA Translation	4.80e-05
Metabolism of RNA	4.91e-05
Response of EIF2AK4 (GCN2) to amino acid deficiency	5.11e-05
Axon guidance	5.84e-05
Influenza Viral RNA Transcription and Replication	9.34e-05

Table S10. Biochemical pathways highlighted in treatment with 1 μ M of benztropine for 24 hours (Benz) compared to vehicle samples, generated by Reactome.

Biochemical pathways - Benz	p-value
-----------------------------	---------

Influenza Infection	2.19e-09
Metabolism of RNA	2.45e-09
Cellular responses to stress	6.94e-08
Influenza Viral RNA Transcription and Replication	1.06e-07
Cellular responses to external stimuli	1.17e-07
M Phase	1.37e-07
CLEC7A (Dectin-1) signaling	2.20e-07
ISG15 antiviral mechanism	2.30e-07
RHO GTPase Effectors	3.27e-07
Host Interactions of HIV factors	3.39e-07
Regulation of mRNA stability by proteins that bind AU-rich elements	5.82e-07
Antiviral mechanism by IFN stimulated genes	6.49e-07
Cell Cycle	8.03e-07
Disorders of transmembrane transporters	8.72e-07
Metabolism of amino acids and derivatives	9.53e-07
Export of Viral Ribonucleoproteins from Nucleus	1.17e-06
Glycolysis	1.53e-06
Glucose metabolism	1.63e-06

10. ANEXOS

10.1 Declaração de bioética e biossegurança

COORDENADORIA DE PÓS-GRADUAÇÃO
INSTITUTO DE BIOLOGIA
Universidade Estadual de Campinas
Caixa Postal 6109. 13083-970, Campinas, SP, Brasil
Fone (19) 3521-6378. email: cpgib@unicamp.br

DECLARAÇÃO

Em observância ao **§5º do Artigo 1º da Informação CCPG-UNICAMP/001/15**, referente a Bioética e Biossegurança, declaro que o conteúdo de minha Dissertação de Mestrado, intitulada ***“Efeito de antipsicóticos e canabidiol em cultura de oligodendrócitos tratados com cuprizona: implicações para mielinização”***, desenvolvida no Programa de Pós-Graduação em Biologia Funcional e Molecular do Instituto de Biologia da Unicamp, não versa sobre pesquisa envolvendo seres humanos, animais ou temas afetos a Biossegurança.

Assinatura: Ana Caroline B. Falvella
Nome do(a) aluno(a): Ana Caroline Brambilla Falvella

Assinatura: [Assinatura]
Nome do(a) orientador(a): Daniel Martins de Souza

Data: 24 de novembro de 2020

10.2 Declaração de direitos autorais

Declaração

As cópias de artigos de minha autoria ou de minha co-autoria, já publicados ou submetidos para publicação em revistas científicas ou anais de congressos sujeitos a arbitragem, que constam da minha Dissertação/Tese de Mestrado/Doutorado, intitulada **"Efeito de antipsicóticos e canabidiol em cultura de oligodendrócitos tratados com cuprizona: implicações para mielinização"**, não infringem os dispositivos da Lei n.º 9.610/98, nem o direito autoral de qualquer editora.

Campinas, 24 de novembro de 2020
